Many recent studies have focused on health effects of fish consumption.[1–5,13,23] Bang emphasized the role of Eskimo diet rich in marine mammal fatty acids, especially seal and whale, and these foods generally were eaten raw.[24] Whether the same health benefits can be anticipated from raw fish and from cooked fish is less clear. Consumption of

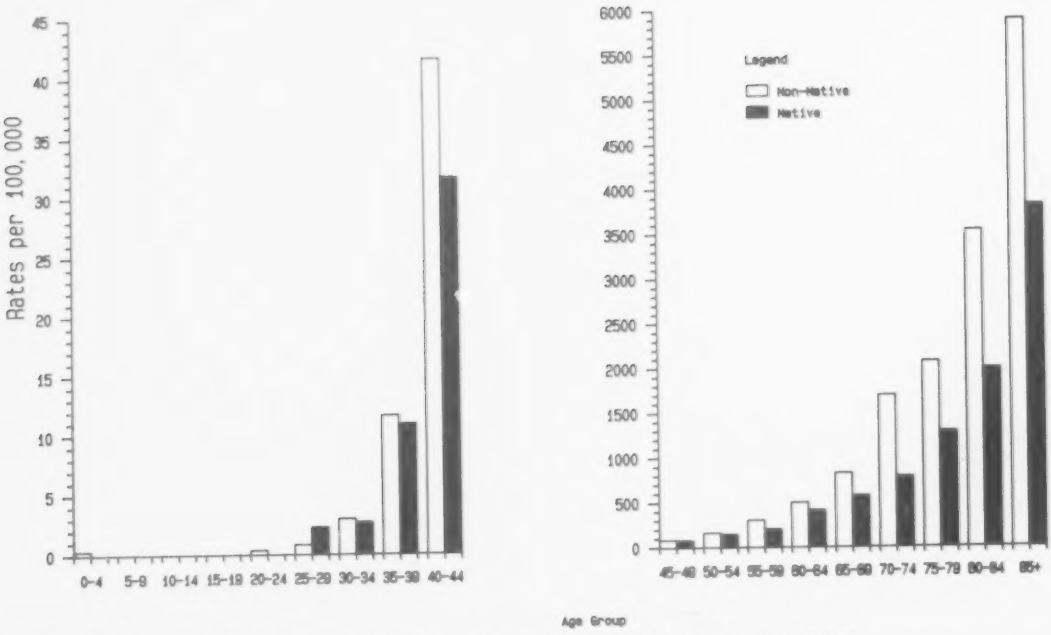

FIGURE 1—Cardiovascular Deaths in Alaska 1980–86 (average annual rate per 100,000 population by age group and race)

salmon remains high and seal, walrus, and whale consumption, both raw and cooked, remains an important part of Alaskan Natives' subsistence diet.

As early as 1900, diet changes among Alaskan Natives were documented as a result of contact with whalers and later with missionaries.[1] Since the 1950s, there has been a dramatic increase in smoking and alcohol consumption. Since the 1960s, western diets increasingly have become available. Since the 1970s, use of snuff has increased.[25] In view of these many life-style changes, it is even more remarkable to find such striking differences in cardiovascular mortality.

The evidence presented here does not establish that the cause of the difference in cardiovascular mortality rates is due to dietary intake of omega-3 fatty acids from marine mammals and fish. It is possible that the differences could be due to genetic factors, or that the observed differences are a result to the effect of competing risks[21,22] acting disproportionately on Natives, or to inaccuracies inherent in death certificate studies. For example, Alaskan Natives may have differences from other Alaskans in the nature and frequency of medical system contacts, the likelihood of receiving care from physicians of similar background and training, availability of diagnostic services, death certification practices in rural compared to urban areas, classification of race on the death certificate, and differences in accuracy of census data. Additional research is needed to pursue accumulating evidence of the beneficial effects that may exist from consumption of omega-3 fatty acids.

Salmonella arizona Infections in Latinos Associated with Rattlesnake Folk Medicine

STEPHEN H. WATERMAN, MD, MPH, GREGORY JUAREZ, MPH, SUSAN J. CARR, MPH, AND LIGA KILMAN, BS

Abstract: In 1987 two Los Angeles County (California) hospitals reported four Latino patients with serious *Salmonella arizona* (*Salmonella* subgroup 3) infections who gave a medical history of taking rattlesnake capsules prior to illness. Capsules supplied by the patients or household members grew *Salmonella arizona*. We reviewed surveillance data for this *Salmonella* species and conducted a case-control study to determine the magnitude of this public health problem. Eighteen (82 percent) of the 22 Latino cases in 1986 and 1987 who were questioned reported ingesting snake capsules compared to two (8 percent) of 24 matched Latino controls with non-subgroup 3 salmonellosis or shigellosis (matched pair odds ratio = 18.0, CI = 4.2, 76.3). An average of 18 cases per year of *Salmonella arizona* were reported in the county between 1980 and 1987. In this investigation the majority of *S. arizona* cases reporting snake capsule ingestion had underlying illnesses such as acquired immunodeficiency syndrome (AIDS), diabetes, arthritis, cancer. The capsules were obtained primarily from Tijuana, Mexico and from Los Angeles, California pharmacies in Latino neighborhoods. Despite publicity and attempts to remove the capsules from sale in California, *Salmonella arizona* cases associated with snake-capsule ingestion continue to occur. (*Am J Public Health* 1990; 80:286–289.)

Introduction

In early 1987, two hospitals in Los Angeles County (California) reported four cases of *Salmonella arizona* (*Salmonella* subgroup 3, formerly *Arizona hinshawii*) infection in Latino patients to the Los Angeles County Department of Health Services. All patients gave a history of ingesting rattlesnake capsules prior to the onset of illness; in all four cases, culture of the rattlesnake capsules from the patients' supply or from their household grew *Salmonella arizona* and other enteric bacteria.[1] The patients had underlying chronic medical illnesses including acquired immunodeficiency syndrome (AIDS) and cancer, and the bacteria were isolated from extragastrointestinal sites (blood, pleural fluid, lymph node). We conducted an investigation to define further the epidemiology of rattlesnake-capsule ingestion and *Salmonella arizona* infections in Los Angeles County.

Methods

Surveillance data for *A. hinshawii* and *S. arizona* infections were reviewed for 1980–87. A matched case-control study was performed in late 1987 and early 1988. All Latino cases of *S. arizona* reported to the Los Angeles County Department of Health Services during 1986 and 1987 were eligible. Each case was matched to one or more persons with either *Salmonella typhimurium*, *Salmonella enteritidis*, or *Shigella*. *Salmonella* controls were chosen from 1986 and 1987 while *Shigella* controls were chosen from 1987. Cases were matched on race and age. Controls were at least 17 years old.

All cases of salmonellosis and shigellosis occurring in Los Angeles County are routinely administered a standard two-page questionnaire covering demographics, clinical information, and potential exposures. These data were supplemented by non-blinded administration of a telephone questionnaire which contained information regarding rattlesnake-pill ingestion, underlying illness, and folk medicine usage. Most interviews were conducted in Spanish by bilingual investigators. Serotype data for all *S. arizona* isolates submitted to the Los Angeles County Public Health laboratories during 1986–87 were reviewed.

Time of exposure was defined as the date to the nearest week, month, and/or year in some cases that the patient reported taking rattlesnake capsules. Since many of the patients were interviewed six months or more after their illness, they often had to estimate these dates. Estimated incubation period was defined as the interval between most recent exposure to rattlesnake pills and date of onset of illness or date of first positive culture, if illness onset date was unclear.

Unless otherwise specified, Mantel-Haenszel matched analysis was used to determine odds ratios and 95 percent confidence intervals (CI).

Results

An average of 18 cases a year of *S. arizona* were reported in Los Angeles County during 1980–87 (Figure 1). The number of cases ranged from nine in 1984 to 33 in 1987. In 1986–87, 45 (85 percent) of 53 such cases were Latino, while 208 (31 percent) of 673 cases with other common *Salmonella* serotypes were Latino (95 percent CI of proportion difference = 0.43, 0.65).

Twenty-two cases were interviewed with the supplemental questionnaire. Not surprisingly, we were able to contact more of the 1987 cases (18 of 29) than 1986 cases (four of 16). The age and geographic distributions of *S. arizona* cases not included were similar to those of interviewed cases. Matched controls included 12 *Salmonella* patients from 1986–87 and 12 *Shigella* patients from 1987. The pool of potential *Salmonella* controls in the proper age range was small. Age matching of cases and controls was ±10 years for 96 percent of the matches; the largest age difference was 14 years.

The median age of cases was 44 years with a range of 16 to 61 years. The male-to-female ratio of interviewed cases was 2.7:1 while that for all Latino *S. arizona* cases was 1.5:1. Cases lived throughout the County but were concentrated in neighborhoods within central Los Angeles. The birthplace or national background of rattlesnake capsule-exposed cases was predominantly Mexico (72 percent).

Eighteen (82 percent) of the 22 cases gave a history of rattlesnake-capsule exposure compared to two (8 percent) of

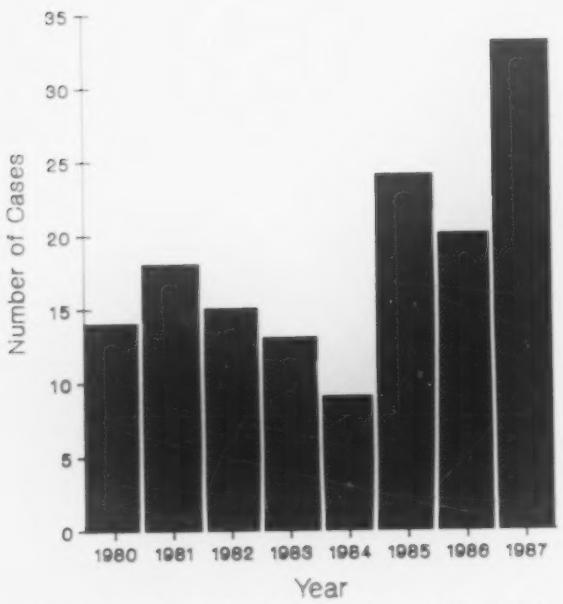

FIGURE 1—Cases of *Salmonella arizona* by Year, Los Angeles County, California 1980–87

24 matched controls (OR = 18.0, CI = 4.2, 76.3). The attributable fraction of *S. arizona* cases due to rattlesnake-capsule exposure in the Latino population is 77 percent.

Ten (56 per cent) of the 18 cases took fewer than 10 capsules over a period of a week or less. Five patients took only two or three pills. One patient ingested capsules daily for four months. The interval between exposure and onset of symptoms or first positive culture ranged from within a week to four years. Eleven (73 percent) of the 15 cases for whom an incubation period could be estimated became ill within three months. Two of the patients with longer estimated incubation periods had perirectal abscesses (Table 1). No correlation was observed between number of pills ingested and incubation period or site of infection.

The reasons patients used rattlesnake capsules included treatments for AIDS, arthritis, blood disorders, cancer, infections, itchy feet, sinus and skin conditions, and diarrhea. The majority of rattlesnake capsules were obtained from Tijuana, Mexico and from Los Angeles, California pharmacies. Patients also reported purchasing rattlesnake capsules in other Mexican border cities, in Central America, from a street vendor, at a local "swap meet" and from a friend. Capsules sold in Los Angeles cost about 20 cents per capsule. Forty-one percent of cases and 54 percent of the controls used other common folk medicines including yerba buena and other herbs and teas.

Feces, blood, and lung or pleural fluid were the most common sites of *S. arizona* isolation (Table 2). All three patients with multiple positive sites of *S. arizona* isolates had AIDS. The antibiogram of one isolate showed sensitivity to ampicillin and all other antibiotics tested.[1]

Fourteen (64 percent) of the 22 cases studied were hospitalized for *S. arizona*-related illness. Two patients had multiple hospitalizations for their infections. One other case was hospitalized for unrelated congestive heart failure. The remaining seven cases were managed as outpatients. The median stay for *S. arizona* cases hospitalized once was 17 days.

Cases with *S. arizona* infection were significantly more likely to have an underlying chronic illness than *Salmonella* controls (OR = 6.7, CI = 1.1, 42.1). The most common chronic conditions among cases included AIDS (five cases), diabetes (four cases), and connective tissue disease (three cases); one case had both diabetes and connective tissue disease, and one case each had heart disease, cancer, and an illness of unknown etiology. Five of six *S. arizona*-infected cases (83 percent) without underlying disease had the bacteria isolated from feces only compared to one of 16 (6 percent) infected chronically ill patients with such an isolation pattern (95 percent CI of proportion difference = 0.33, 1.0). In unmatched analysis, controlling for chronic illness, cases were more likely than *Salmonella* controls to have an extragastrointestinal site of infection (OR = 26.3, CI = 1.4, 500). Three of six *S. arizona* patients without underlying

TABLE 1—Summary of Four Latino *S. arizona* Cases with Estimated Incubation Periods Greater Than Three Months, Los Angeles County, 1986–87

Case No	Date of Exposure to Rattlesnake Capsules	Date of First Positive Culture	Site of Positive Cultures	Chronic Illness	Comment
7	March 1987	8.13.87	Lung, urine	AIDS	Patient diagnosed with AIDS January 1987. Because the patient had chronic fever, the date of onset with regard to *S. arizona* is unclear.
17	1982	3.26.87	Perirectal Abscess	Adult onset diabetes mellitus and rheumatoid arthritis	Perirectal abscess first developed in June 1986 and recurred. Patient gave no history of symptoms which could be related to *S. arizona* infection prior to this time.
20	Early 1986	12.12.86	Perirectal Abscess	None	The date of onset is unclear. Patient took rattlesnake capsules for four months.
21	1985	9.8.86	Feces	None	Patient was hospitalized for 12 days during August 1986 for spinal surgery and received prophylactic antibiotics. Patient developed diarrhea during the hospitalization.

TABLE 2—Sites of Positive Cultures for *Salmonella arizona* by Disease Status in 22 Latino Patients, Los Angles County, 1986–87

Site of Isolate	No. Cases (%)			
	Nomal Host (n = 6)	AIDS (n = 5)*	Other underlying conditions (n = 11)	Total (n = 22)
Feces	5 (83)	2 (40)	1 (9)	8 (36)
Blood		3 (60)	3 (27)	6 (27)
Lung or pleural fluid		2 (40)	2 (18)	4 (18)
Urine		1 (20)	2 (18)	3 (14)
Perirectal abscess	1 (17)		1 (9)	2 (9)
Wound			2 (18)	2 (9)
Lymph node		1 (20)		1 (5)

*One patient had positive blood and feces cultures, a second patient has positive lymph node, pleural fluid and feces cultures, and a third patient had positive lung and urine cultures.

illness (50 percent) were hospitalized with their infection.

Death occurred in six cases and one control. Three of the *S. arizona*-infected patients who died had AIDS. *S. arizona* infection was not listed as the direct cause of death in any of the cases. However, three patients had positive blood cultures for *S. arizona* within two months of their death and the infection appears to have exacerbated their condition.

Eighteen of 49 (37 percent) *S. arizona* isolates from the Latino cases were either serotype 3a 53:z_4,z_{23},z_{32}:-(n = 9) or 3a 21:z_{29}:-(n = 9) compared to none of 10 isolates serotyped from non-Latino patients in 1986 and 1987 (95 percent CI of proportion difference = 0.18, 0.57, Table 3). Both of these serotypes were cultured directly from rattlesnake capsules as were two other serotypes, 3a 61:1, v:1,5,7 and 3b 50:4:z, which were also isolated from both Latino and non-Latino patients. The 10 isolates of the latter two serotypes were all from feces, whereas 17 (94 percent) of the isolates of the former two serotypes were from extragastrointestinal sites.

Discussion

This investigation of Los Angeles County residents shows that human *S. arizona* cases are relatively common and that over three-fourths of recent *S. arizona* infections in Latinos are linked to rattlesnake capsules. Rattlesnake-capsule ingestion by persons with invasive *S. arizona* infection has been previously documented in case reports.[1–4] All of these cases were Latino patients who resided in the Southwest and had underlying disease.

Capsules cultured from *S. arizona* cases or households have been positive for *S. arizona* and other enteric bacteria.[1,2] The capsules are made of dried ground rattlesnake flesh and are known by several names including polvo de vibora, carne de vibora, or vibora de cascabel. The ingestion of snake preparations is an old popular folk remedy of Mexico and Central America and is used for a variety of medical conditions.[1–5] In this investigation, the majority of patients acquired the capsules from the border city of Tijuana, Mexico and from Los Angeles, California pharmacies or "farmacias" and "boticas" which serve the Latino community.

Reptiles constitute the major reservoir of *S. arizona*.[6–9] Other animal sources from which this bacterial species has been isolated are various fowl and rodents as well as opossums, goats, swine, dogs, and minks.[10,11] Foodborne outbreaks of *S. arizona* gastroenteritis have been reported associated with ice cream, cream pie, eggs, and egg powder.[12,13] Extragastrointestinal disease has been reported in patients with liver abscesses, septic arthritis, brain abscesses, pleural fluid infection, osteomyelitis, and cholecystitis.[12,14–16]

This surveillance study and case reports[1–4] indicate that underlying medical conditions are present in the majority of *S. arizona* cases who ingest rattlesnake capsules. Our findings suggest that *S. arizona* infections are at least as likely as other *Salmonella* serotypes to result in septicemia and focal

infections in patients with significant underlying disease.[17–19] The predisposing disease process alone or in association with treatments such as corticosteroids, chemotherapy, radiotherapy and antibiotics can interfere with host-resistance mechanisms. Edwards, *et al*,[12] have suggested, on the basis of isolation site proportions, that *S. arizona* may be more invasive than other *Salmonella* species. Our analysis using *Salmonella* controls and controlling for chronic disease is consistent with this possibility as is the 50 percent hospitalization rate in cases without underlying illness. Further, our data on *S. arizona* serotype distribution by isolation site and that of Weiss, *et al*,[20] suggest that invasiveness may be serotype-specific. In both studies, serotype 61:1,v:1,5,7 stands out as relatively noninvasive.

Most of the patients in this study ingested fewer than 10 rattlesnake capsules. Riley, *et al*,[1] found 10^5 *S. arizona* organisms per gram in one sample. Capsules weigh an average of 700 mg and, thus, the infectious dose of *S. arizona* may be as low as 10^5 or 10^6 organisms. For the many patients with reduced resistance who take rattlesnake capsules, the infectious dose may be even lower.

Although the incubation period for *Salmonella* gastroenteritis is usually 24–36 hours, four study persons apparently were indolently infected for months to years before developing signs of illness or before positive cultures were obtained. Prolonged intestinal carriage of *Salmonella* bacteria is a well recognized phenomenon; chronic illness or other factors such as surgery or disruption of intestinal flora due to antibiotics may have triggered active infection in these patients.[21] Two persons, one with underlying illness and one a normal host, had perirectal abscesses which could have been present for some time but were undetected. While recall and interviewer bias is possible, we believe the histories of rattlesnake capsule ingestion are accurate because interviewers described or denied such exposure without hesitation.

Five cases who were exposed to rattlesnake capsules had an underlying condition of AIDS. Investigators at Los Angeles County/University of Southern California Medical Center have recently reported on four of these patients.[1] Human immunodeficiency virus (HIV) infection has been shown to predispose patients to serious *Salmonella* infections.[22,23] Salmonellosis in persons with AIDS is characterized by widespread infection, bacteremia, and relapse even with standard antibiotic therapy. Through September 1988, over 900 cases of AIDS in Latinos have been reported in Los Angeles County, and the proportion of Latino AIDS cases has increased 133 percent from 9 percent to 19 percent between 1982 and 1988.* Thus, the dangers of rattlesnake-capsule exposure should be emphasized to Latinos due to their increasing pool of AIDS victims and the propensity of some to use folk remedies.

Physicians and health care workers should be aware of the potential for *S. arizona* infection from ingesting rattlesnake capsules and the prevalence of this practice. The State of California Department of Health Services Food and Drug Branch has taken action to prevent further distribution of the products and to remove the capsules from pharmacies and markets known to distribute them. Distributors were also requested to recall the products. Perhaps because of these actions and publicity in both Spanish and English, only 12 *S. arizona* cases linked to rattlesnake capsule ingestion were reported in Los Angeles County in 1988. Continued occurrence of cases is not surprising given the availability of rattlesnake pills in local Latino neighborhoods and along the US-Mexico border. Health agencies and community groups should pursue education of the Latino population about the risks and absence of medical benefit from rattlesnake capsules.

*Lieb L. AIDS Epidemiology Program, Los Angeles County Department of Health Services, personal communication, 1988.

ACKNOWLEDGMENTS

We are grateful to Juanita Orta, Sally Mendoza, Esther Parker, Frank Sorvillo and Jim Thomas for administrative and technical assistance. We also thank hospital infection control nurses and public health nurses who helped in data collection. The California State Department of Health Services Microbial Diseases Laboratory performed *Salmonella arizona* serotyping on the Los Angeles County isolates.

Use of Medical Care for Chest Pain: Differences between Blacks and Whites

David S. Strogatz, PhD

Abstract: Data from a 1980, community-based survey of adult residents of Edgecombe County, North Carolina were analyzed to examine differences between Blacks and Whites in the reported use of medical care after experiencing chest pain. Of all adults (N=302) with chest pain in the year prior to interview, 49 percent of Blacks and 27 percent of Whites did not see a physician following the chest pain (difference = 22%, 95% CI = 12, 33). A multivariable analysis found that although the association between race and utilization was reduced at poverty levels of income, it was not explained by differences in demographic characteristics, health status or other dimensions of access to care. (*Am J Public Health* 1990;80:290–294.)

Introduction

Coronary heart disease (CHD) mortality rates for Black Americans exceed those of Whites at ages 25–64 and are similar to the rates of Whites for all ages combined.[1–3] In contrast, population rates of CHD occurrence based on cases from hospital discharge surveys are lower for Blacks than for Whites.[4,5] The inconsistency between the mortality and hospitalization data may be due to bias in detection and measurement, but it may also reflect an excess of CHD deaths among Blacks before the hospital is reached. A hospital surveillance study of CHD in Newark determined that Blacks were more likely to be dead on arrival at the hospital.[6] A study in urban and rural areas of South Carolina also reported that Blacks had higher rates of out-of-hospital mortality from acute myocardial infarction.[7] In community-based studies of sudden death, Blacks were found to be at greater risk than Whites in Charleston,[8] New Orleans,[9] and Nashville,[10] although not in Baltimore[11] where there was essentially no Black-White difference in the occurrence of sudden death.

Among those who do not die immediately, Blacks and Whites may differ by how soon medical care is received following the onset of symptoms. The National Ambulatory Medical Care Survey found that Blacks had fewer office visits for CHD and other diseases of the circulatory system.[12] Compared to Whites, Blacks are far less likely to be seen by a cardiologist, to have coronary angiography performed, and to undergo coronary artery bypass surgery.[12–15] These differences persist even among hospitalized patients, controlling for the clinical severity of disease.[14–17]

Less is known about Black-White differences in patients' knowledge of symptoms and decisions to seek care, an increasingly salient issue with the emergence of thrombolytic agents (e.g., streptokinase, tPA) for treatment in the early phase of myocardial infarction. A community survey on CHD conducted among Black residents of a southern US city found low levels of knowledge about CHD, its signs and symptoms.[18] In a comparison of Blacks and Whites living in Minneapolis-St. Paul, Blacks were less informed about the symptoms of myocardial infarction.[19] A study of attitudes about a variety of hypothetical symptoms found that Blacks and Whites had similar perceptions about how urgently to seek care for stable or unstable angina.[20] However, interviews with a consecutive series of Black patients hospitalized with acute myocardial infarction revealed that the average time between onset of symptoms and arrival at the hospital exceeded the times reported in similar investigations of White patients.[21] These preliminary findings indicate that gaps in knowledge and delays in receiving care may contribute to Black-White differences in pre-hospital mortality from CHD.

The purpose of this paper is to compare reported use of medical care by Blacks and Whites who experienced chest pain and to examine the degree to which demographic characteristics, access to medical care, and health status modified or accounted for Black-White differences in care-seeking behavior.

Methods

The data for these analyses were collected as part of the 1980 baseline survey of the Edgecombe County (North Carolina) High Blood Pressure Control Program. One thousand dwellings were randomly chosen, and interviews were sought with all members of the selected households who were 18 years of age or older. Data were collected from 2,029 individuals (1,085 White, 944 Black), representing an overall response of 91 percent. Additional information on the study population and procedures has been published.[22]

History of chest pain and associated use of medical care were measured by answers to a pair of questions from a larger set of similar items used to derive the symptom-response ratio, a need-based measure of utilization of health services.[23] During the interview, each individual was asked if he or she had experienced "repeated pains in or near the heart" at any time during the last 12 months and, if so, whether a doctor had been seen for it, in the past year or some time earlier. From this question, the 319 respondents (147 White, 172 Black) with chest pain in the past year were divided into three groups: 1) those who had seen a doctor for chest pain within the past year; 2) those who had seen a doctor for chest pain at some time, but not in the past year for this most recent episode; and 3) those who had never seen a doctor for their chest pain.

The baseline interview also included a series of questions concerning various barriers to medical care. As described in detail elsewhere,[24] these questions were used to measure four dimensions of access to care identified by Penchansky and Thomas[25]: *accessibility* (convenience of location of health services); *accommodation* (ease in getting an appointment); *affordability* (ability to pay for care); and *acceptability* (how well respondents get along with providers). Each dimension

of access to care was represented by a structural score, a psychological score, or both. The structural access variables referred to rank ordering on tangible entities (e.g., distance to be traveled, time spent waiting, money or insurance at one's disposal), with a high score denoting good access. Psychological access referred to reported dissatisfaction on each dimension; scores on measures of psychological access represent the percent of individuals expressing dissatisfaction. The questions on access to care were answered by all persons who reported having a regular source of medical care. Fifteen of the 319 individuals with chest pain (3 White, 12 Black) did not have a regular source of care and therefore were not included in analyses involving these variables. Two other individuals had missing data on other variables of interest, leaving a total of 302 in the final analysis.

Other potential predictors of utilization which were measured at baseline and included in the analysis were age, sex, self-perceived health as measured by the Current Health Scale (CHS),[26] and reported history of myocardial infarction ("Have you ever had a heart attack?") and current antihypertensive treatment ("Are you now taking medicine for high blood pressure?")

The effect of race on the use of medical care for chest pain was initially characterized by an observed (unadjusted) difference between proportions with a corresponding confidence interval.[27] This measure conveys the potential impact of strategies to eliminate the association between race and utilization. Further analyses were conducted using linear multiple regression to estimate the Black-White difference adjusted for demographic characteristics, measures of health status, and dimensions of access to care. To highlight the contrast in use of care, these analyses were restricted to the two groups most different in utilization: individuals seen *during the past year* when chest pain occurred (group 1 defined above) vs individuals who were *not seen at all* for their chest pain (group 3). A backward stepwise procedure (with $p = .05$ to remain) was run to evaluate product terms combining race with each covariate.[27] Main effect terms for race and for all covariates were automatically included in the model. With the linear regression analysis, the coefficient for the variable representing race was equal to the adjusted difference between the percent seeking care for Whites and the percent seeking care for Blacks. Race-specific regression models were also computed to assess the predictive importance of the covariates.

Results

The use of medical care by adults after they experienced chest pain is summarized in Table 1. Almost half of all Blacks with repeated pain near the heart never saw or discussed this with a doctor, compared to 27 percent of Whites (difference between percentages = 22%, 95% CI: 12, 33).

TABLE 1—Association between Race and Use of Medical Care by Adults Experiencing Chest Pain in the Past Year: Edgecombe County, NC, 1980

Use of Medical Care for Chest Pain	Black		White	
	N	(%)	N	(%)
MD seen in past year	35	(22)	67	(47)
MD seen, not in past year	45	(28)	38	(26)
MD never seen	78	(49)	39	(27)
Total	158	(100)	144	(100)

Subsequent analyses examined the distribution and influence of the covariates in addition to the Black-White difference in utilization. These analyses were restricted to individuals who either had seen a physician for chest pain in the past year (35 Blacks, 67 Whites—top row of Table 1) or had never seen a physician for chest pain (88 Blacks, 41 Whites). The characteristics of these adults are shown in Table 2. In the overall comparison of Blacks and Whites with chest pain, Blacks were younger, appeared to be healthier (by self-perception and history of myocardial infarction), had worse structural access to their source of medical care, and (except for cost) had somewhat more dissatisfaction with their source of care.

In the unadjusted data of both Blacks and Whites, utilization in response to chest pain was associated with older age, worse perceived health, and a history of myocardial infarction or current antihypertensive therapy. In contrast, crude associations between dimensions of access to care and utilization of care appeared to differ by race. Among Whites with chest pain, those adults who sought care had better structural access and less dissatisfaction with care. Among Blacks, care seeking was not associated with psychological access and had an inverse relationship with two dimensions (affordability, accommodation) of structural access.

The results of the multivariable analyses are given in Table 3. For Black adults, physician visits for chest pain were independently associated with history of myocardial infarction, current antihypertensive treatment, and having experienced delays in the past when trying to make an appointment (low structural accommodation). These variables were related to utilization in the same direction for Whites, but were less pronounced. The only predictor of significance for Whites was worse self-perceived health. Older age and relative satisfaction with the appointment process (psychological accommodation) were also associated with physician visits by Whites.

The predictors from the race-specific models were similarly identified in the model combining Blacks and Whites. The only statistically significant interaction term was the product of race and structural affordability (an index which combines information on income and insurance[24]). The race-specific models show that structural affordability was a weak positive predictor of utilization for Whites and negative for Blacks. The impact of this interaction on the Black-White difference in utilization can be illustrated for selected values of structural affordability (where the difference between percent utilization by Blacks and percent utilization by Whites equals $0.128 - 0.052 \cdot$ structural affordability). Among poor individuals (e.g., annual family income $\leq$ $5,000, no health insurance: structural affordability = 4), Whites were more likely than Blacks to have seen a physician but the difference between the percentages was relatively small (8 percent). This difference between percentages of Whites and Blacks who saw a physician was 18 percent at the median value (6) for structural affordability in this sample. At a high level of resources for this community (e.g., annual family income = $20,000, insurance pays for a portion of office visit and medication costs: structural affordability = 10) the difference was 39 percent.

Discussion

These data showed the expected Black-White difference in the use of medical care for chest pain. This difference increased with greater structural affordability (i.e., greater

family income and health insurance). Interpretation of these results requires recognition that measures of socioeconomic status may not have the same meaning and implications for Blacks and Whites.[28] For example, Blacks generally have had less opportunity than Whites to translate educational achievement into better jobs, more stable employment, and higher income,[29] so comparisons of Blacks and Whites with the same years of education can be misleading. Similar problems arise when comparing Blacks and Whites at the same level of income without adjustment for differences in family size, purchasing power, and property, all of which would tend to accentuate racial inequality in income.[30] The Black-White gap in utilization at higher levels of structural affordability in part may reflect differences in economic resources which may not be reflected by family income. These problems do not explain the inverse relationship between structural affordability and utilization among symptomatic Black adults. It may be a chance association in these data. Alternatively, social support is directly related to economic resources in this population[31]; perhaps the more economically advantaged Blacks rely more on social support networks for advice on health. Untapped dissatisfaction with past medical visits may also be reflected in lower utilization by those individuals with somewhat more income or insurance. As others have reported, the elimination of racial differences in the use of medical care will require more than just modifying the ability to pay for services.[32,33]

Other possible explanations for the Black-White difference in utilization include differences in perceptions about the seriousness of the symptom and the potential efficacy of medical care. Compared to Whites, Blacks may be less likely to perceive chest pain as serious enough to warrant immediate medical attention. Berkanovic and Telesky[34] suggest that the pronounced association between severity of symptoms and utilization for Blacks may be a vestige of past circumstances in which only the most disabling conditions could serve as justification for interruption of one's duties in order to seek care. This habit may persist today even for individuals who have more resources or autonomy over their personal lives. Studies of Whites with chest pain suggest that

both the severity of the symptom and an individual's flexibility to respond at the time of symptom onset will contribute to delay in receiving care.[35,36]

Blacks and Whites also may view the likely efficacy of visiting the doctor differently. Perceived efficacy, an important predictor of care-seeking by symptomatic individuals,[37,38] was different in this population when treatment for hypertension was assessed.[24] Hypertensive Black adults were found to have less confidence in the net benefit of anti-hypertensive medication, and this attitude was associated with a greater likelihood of being untreated for diagnosed hypertension.

There are several limitations in these data. First, the question used to signify chest pain may not be measuring ischemic pain, and the meaning may vary by race. In Blacks and Whites, self-reported chest pain was associated with history of myocardial infarction and with established predictors of CHD (age, hypertension, and cigarette smoking), suggesting some common features of the measurement of the symptom. The instrument for the symptom-response ratio also included separate questions on indigestion and abdominal pain to avoid misclassification of chest pain in respondents with gastrointestinal symptoms.

Another problem is that the perceptions about health or access to health care may have been a product, as well as a determinant, of use of health services. Any resultant overestimation of the association between covariates and utilization (either because of selective recall or the influence of utilization on perceptions) would probably lead to an underestimate of the residual association between race and utilization. Despite this possibility, substantial Black-White differences were found in the multivariable analysis.

These findings require confirmation, e.g., in individuals from a defined population who present to the emergency room with acute myocardial infarction. The sequence of perceptions and behaviors from initial symptom to arrival at the hospital should be characterized. To the extent possible, similar data should be collected from witnessed instances of fatal CHD. Such a study was conducted 20 years ago in a White population[39]; replication in a Black or biracial community would be informative. The knowledge of symptoms of CHD also should be measured in community-based surveys related to cardiovascular disease.

Award in Honor of Dr. Fred L. Soper (1893–1976) to Recognize Publications in the Field of Inter-American Health

A special award created by friends of Fred L. Soper, Director of the Pan American Health Organization (the World Health Organization Regional Office for the Americas) from 1947 to 1958, has been established in recognition of his outstanding contributions to health in the Americas.

In addition to his service with PAHO/WHO, Dr. Soper played a major role in the fight against yellow fever and other infectious diseases in Brazil as part of his work with the Rockefeller Foundation in the 1920s and 1930s and in the control of typhus in North Africa and Italy during the Second World War. He was one of the major figures of the century in inter-American health.

The award will be presented annually to the author or authors of an original scientific contribution comprising new information on, or new insights into, the broad field of public health, with special relevance to Latin America or the Caribbean or both. This may consist of a report, an analysis of new data, experimental or observational, or a new approach to analyzing available data. Preference will be given to studies involving more than one discipline and to papers related to infectious disease, a life-long concern of Dr. Soper. Review papers are eligible if their conclusions deal directly with policy primarily affecting Latin America or the Caribbean.

Papers that have been published or are suitable for publication in the *Boletín* of the Pan American Health Organization will be given priority, but meritorious papers published in other journals readily available to Latin American health personnel will also be eligible.

The award fund will be administered by the Pan American Health and Education Foundation (PAHEF) which will receive voluntary contributions designated for the purpose and hold them in a separate fund. The winner(s) of the award each year will be nominated by an awards committee consisting of experts designated by PAHO and PAHEF, and will be approved by the PAHEF Board of Trustees.

Papers submitted by or on behalf of their authors may be considered for the Fred L. Soper Award. The first award will be made during 1990; in order to be considered, all papers must be received by March 31, 1990. All submissions, as well as all monetary contributions to the Award Fund should be sent to:

Beliefs about AIDS, Use of Alcohol and Drugs, and Unprotected Sex among Massachusetts Adolescents

RALPH W. HINGSON, ScD, LEE STRUNIN, PhD, BETH M. BERLIN, MS, AND TIMOTHY HEEREN, PhD

Abstract: In August 1988, 1,773 Massachusetts 16–19-year-olds were surveyed by telephone using anonymous random digit dialing; response rate 82 percent. Logistic regression tested whether alcohol and drug use, perceived susceptibility to human immunodeficiency virus (HIV), severity of HIV if infected, effectiveness of condoms in preventing infection, barriers to condom use, and behavioral cues such as exposure to media or personal communication about acquired immunodeficiency syndrome (AIDS) were independently related to condom use. Among sexually active respondents, (61 percent of those interviewed) 31 percent reported always using condoms. Respondents who believed condoms are effective in preventing HIV transmission and worried they can get AIDS were 3.1 and 1.8 times, respectively, more likely to use condoms all the time. Respondents who carried condoms and who had discussed AIDS with a physician were 2.7 and 1.7 times, respectively, more likely to use them. Those who believed condoms do not reduce sexual pleasure and would not be embarrassed if asked to use them were 3.1 and 2.4 times, respectively, more likely to use condoms. Teens who averaged five or more drinks daily or used marijuana in the previous month were 2.8 and 1.9 times, respectively, less likely to use condoms. Among respondents who drink and use drugs, 16 percent used condoms less often after drinking and 25 percent after drug use. Those counseling adolescents about HIV should assess and discuss beliefs outlined in the Health Belief Model, as well as their alcohol and drug use. (*Am J Public Health* 1990; 80:295–299.)

Introduction

One-fifth of reported AIDS (acquired immunodeficiency syndrome) cases in the United States have been in the 20–29 year age group.[1] Given the incubation period, many of those persons were infected during their high school years or shortly thereafter.

Knowledge of behavioral risks for AIDS does not prompt all at risk to change their behavior.[2] Most older teens in Massachusetts have learned the principle modes of human immunodeficiency virus (HIV) transmission, and adolescent condom use has increased since 1986.[3,4] However, two-thirds of sexually active 16–19 year olds surveyed there in the fall of 1988 reported sexual intercourse in the past year without the use of condoms.[4] Nationally, teenagers account for one-fourth of sexually transmitted disease cases.[5]

Educators need to move beyond imparting knowledge about modes of HIV transmission to change adolescent behavior. A specific set of beliefs described in the Health Belief Model has been found to predict behaviors to avoid other health risks,[6] and has been hypothesized to also predict whether someone will adopt behavior to avoid HIV transmission.[7] Persons who believe they are personally susceptible to HIV exposure, the consequences of exposure are severe, protective measures such as condom use are effective in preventing transmission, and perceive few barriers to the adoption of condom use may be more likely to adopt such behavior to avoid HIV transmission. According to this model, people make a rational cost-benefit analysis when trying to decide whether to adopt preventive behavior. Actual changes in behavior may then be stimulated by cues to action such as educational messages or learning that someone they know has AIDS.

However, among adolescents, sexual encounters may be unplanned and also often occur after drinking or drug use. Exploratory studies in San Francisco indicate gay men are more likely to have unprotected intercourse after alcohol and drug use.[8] Whether this applies to heterosexuals warrants exploration. Because these and other factors may mitigate against adolescents making a cost-benefit analysis about HIV and condom use before each sexual encounter, it is important to assess whether the beliefs described in the model do indeed predict which adolescents will use condoms and, if so, which beliefs are the strongest independent predictors of use. It is also important to assess whether alcohol and drug use are negatively related to condom use and, if so, why.

This Massachusetts statewide study of adolescents assessed:

- whether beliefs outlined in the Health Belief Model are significantly associated with condom use among sexually active adolescents;
- which beliefs are the strongest independent predictors of condom use after controlling for social and demographic characteristics of respondents;
- whether condom use is less likely after drinking and drug use; and
- whether those who use condoms less often after drinking and drug use have different characteristics and beliefs about HIV transmission.

Methods

In September 1988, a statewide anonymous random digit dial telephone survey of 16-to-19-year-olds was conducted in Massachusetts using methods developed by Waksberg.[9] Within each household, one adolescent was randomly selected using methods developed by Kish.[10] The survey of 1,773 adolescents (response rate 82 percent) was conducted in English and Spanish and explored respondent knowledge and beliefs about HIV transmission; alcohol, marijuana, and other illegal drug use; and behavior change in response to the AIDS epidemic. The study specifically asked respondents beliefs that are identified in the Health Belief Model (see Appendix for details).

In addition, respondents were asked their age, level of education, gender, whether their sexual activity was with males, females or both, and the number of sexual partners

they had in the past year. Chi square analyses tested whether individual beliefs outlined in the Health Belief Model and alcohol and drug use were associated with condom use. Condom use was classified as: never used condoms, use condoms some of the time, always used condoms. Stepwise logistic regression analysis[11] tested which beliefs were the strongest independent predictors of condom use after considering demographic characteristics, alcohol and drug use, and numbers of sexual partners, and whether alcohol and drug use were independently related to condom use. Condom use was dichotomized as always used condoms versus sometimes or never used. Odds ratios and confidence intervals were calculated. The chi square test for symmetry[12] assessed whether individuals were less likely to use condoms after drinking and drug use. Finally, chi square analyses tested for differences in characteristics and beliefs of adolescents who used condoms less often after drinking or drug use.

Results

Bivariate Analysis

Condom use according to respondent characteristics—Among the 1,773 adolescents interviewed, 61 percent (n = 1,050) reported having had intercourse in the previous year. Two percent of males reported homosexual behavior. Among sexually active teens, 31 percent (n = 320) reported always using condoms, 32 percent (n = 345) sometimes, and 37 percent (n = 385) never used condoms. Males were more likely than females to report always using (34 percent vs 26 percent). Thirty-nine percent of 19-year-olds compared to 29 percent of 16-year-olds were more likely to always use condoms. Thirty-one percent of Whites, 28 percent of Blacks, and 39 percent of Hispanics, but only 7 percent of persons from other racial backgrounds, always used condoms. Condom use varied by previous numbers of sexual partners (Table 1). Respondents who reported only one partner in the last year were much more likely to never use condoms than those who had more partners. However, respondents who reported 10 or more partners were the least likely to always use condoms.

TABLE 1—Condom Use Among Sexually Active Massachusetts Teenagers According to Numbers of Sexual Partners

Number of Sexual Partners (past year)	% Never Use Condoms N = 380	% Sometimes Use Condoms N = 337	% Always Use Condoms N = 316	
1 (N = 549)	46	26	29	
2–4 (N = 370)	29	35	36	(p<.0001)
5–9 (N = 85)	22	52	26	
10+ (N = 28)	8	75	17	

Adolescents who averaged five or more drinks daily were somewhat less likely to always use condoms than abstainers (29 vs 35 percent) as were persons who smoked marijuana at least weekly (22 vs 32 percent of abstainers). Persons who used other psychoactive drugs in the past month were also less likely to always use condoms than those who did not (20 vs 32 percent).

Condom use according to respondents' health beliefs—On most dimensions of the Health Belief Model, bivariate associations with condom use were observed. Respondents were more likely to always use condoms if they felt susceptible to AIDS; believed condoms are effective; perceived few barriers to condom use; and were exposed to more cues to action (Tables 2–4).

Multivariate Analysis

Health beliefs—We used stepwise logistic regression analysis to assess which beliefs were the strongest independent predictors of whether sexually active adolescents always used condoms (Table 5). Variables under barriers to use were the strongest predictors of condom use. Perceived

TABLE 2—Proportion of Massachusetts Adolescents Who Always Use Condoms According to Their Perceived Susceptibility to HIV and AIDS (N = 1,050)

Perceived Susceptibility	N	% Always Use Condoms	Relative Risk*	(95% C.I.)*
How likely is a female to acquire the AIDS virus during intercourse with an infected male?

*When a variable had more than two categories the extremes were compared.

effectiveness of condoms, and how much respondents worried about acquiring AIDS also independently predicted use. Also, adolescents who spoke to physicians about AIDS were more likely to use condoms.

Of the demographic and behavioral variables entered into the same regression analysis, age predicted always using condoms, with younger persons more likely to use condoms. Race was also predictive of use, with Whites more likely than Blacks or other non-Whites to use condoms. Independent of beliefs, number of sexual partners, education, and gender were not related to condom use.

Drinking and drug use—Adolescents who drank five or more drinks daily (5 percent of sexually active adolescents)

White vs Other	2.91	(1.02,8.27)

and those who used marijuana in the past month (29 percent of sexually active adolescents) were 2.8 and 1.9 times, respectively, less likely to use condoms. To further assess whether drinking and drug use independently influenced condom use, we asked respondents if they had intercourse in the past six months after drinking and after drug use. Those who had intercourse were then asked how often they used condoms when having sex after drinking and after drug use, and how often they used condoms when they had not been drinking or taking drugs.

Sixteen percent of adolescents who said they had sex after drinking reported using condoms less often after drinking than when not drinking (73/465) (Table 6) and 25 percent who said they had sex after drug use reported using condoms less often after using drugs (40/160) (Table 7).

Compared to other sexually active adolescents who drink, those who use condoms less often after drinking were significantly more likely to believe HIV sexual transmission, if one partner is infected, is only a little likely from males to females (10 vs 2 percent), females to males (19 vs 2 percent), or between males (5 vs .1 percent). They were also more likely to believe it is very true that condoms reduce pleasure (27 vs 15 percent), to have sex after drug use (45 vs 28 percent), and to have had 10 or more sexual partners in the past year (11 vs 4 percent).

Compared to other sexually active adolescents, those

Use condoms less often after taking drugs 40/160, 25%

who used condoms less often after other psychoactive drug use also more often believed it very true that condoms reduce pleasure (34 vs 16 percent). They tended to be younger (45 vs 21 percent age 16), more likely to have dropped out of school (25 vs 8 percent), and much more likely to believe HIV is transmitted in ways it is not, e.g., by sharing eating and drinking utensils, and shaking hands (both 9 vs 1 percent).

Discussion

Telephones are owned by over 95 percent of households in Massachusetts, but low-income racial/ethnic minority households are the least likely to own phones. Because low-income households are at the highest risk of AIDS, this survey may slightly overestimate respondents' knowledge about AIDS and underestimate prevalence of behaviors that pose risk of HIV transmission.

A study of adults in Montreal found beliefs in the Health Belief Model predicted safer sex practices among adults.[3] This study suggests that some beliefs about HIV transmission and AIDS identified in the Health Belief Model predict whether adolescents will use condoms. Concern about acquiring AIDS, beliefs that condoms are effective in preventing HIV transmission, and speaking to a physician about AIDS predicted use. Barriers to use such—i.e., beliefs that condoms reduce pleasure, are embarrassing to use, or that respondents do not routinely carry condoms—were also highly predictive of not using condoms.

Variables concerning perceived severity of HIV infection were not, however, significant independent predictors of use. Although bivariate analyses revealed these variables were related to condom use, the overwhelming majority of respondents believed there is no cure for AIDS, and that infected persons will die from AIDS. Consequently, those variables did not explain much variation in condom use.

Beliefs about AIDS accounted for approximately one-tenth of variation in use. While a sizable fraction, this means that numerous other issues relate to use. In this study, use was less among heavy drinkers and frequent drug users suggesting the limits of rational cost-benefit beliefs in determining condom use when people are intoxicated.

A study of adolescents in Scotland found that respondents' first sexual intercourse was more likely to have occurred without the use of a condom if they had been drinking.[14] In this Massachusetts study, even among the same individuals, use of condoms were less likely after drinking and drug use suggesting that concerns about condom use may seem less pressing when people are intoxicated.

Many other factors not explored in this survey and not directly related to health beliefs about condoms and AIDS or HIV may also influence whether adolescents use, or will use, condoms. These include the ability to discuss contraception with sexual partners; perceptions of which partner's responsibility it is to purchase and use contraceptives; beliefs about abortion; concerns about other sexually transmitted diseases; beliefs and desires for pregnancy; beliefs about the efficacy of condoms relative to other contraceptives; issues of ambivalence about being prepared for sexual intercourse; influence of peers and perceptions about whether condom use is increasing among peers; advice received about family planning; perceptions of medical care providers and the adequacy or sensitivity of their advice; and cultural and religious beliefs. Beliefs and preferences of partners on all the issues cited above could also influence condom use. Also, although 77 percent of adolescents reported that they would not be embarrassed if a partner asked that condoms be used, this was an abstract response to a question most had never been asked. If one sex partner asks another to use a condom, questions of trust and fidelity could easily surface for both partners.

Nonetheless, this study suggests that the Health Belief Model provides a useful set of beliefs about AIDS to explore among adolescents and to target in efforts to increase condom use. Not only should educators try to change beliefs through education about personal susceptibility to the virus,[10] they should try to heighten perceived effectiveness of condoms by teaching adolescents which types of condoms offer the most protection, and how to avoid mistakes in using condoms that could reduce their effectiveness. Issues of embarrassment should be addressed possibly by role playing of discussion with sexual partners about AIDS and condoms, and efforts could be undertaken to make condoms more easily accessible to both male and female adolescents.

Finally, alcohol and drug use may reduce the likelihood that adolescents will use condoms. The array of educational, counseling, and legal approaches to reduce adolescent alcohol and drug consumption may thus have a particularly important influence on HIV transmission.

APPENDIX

Questions Used in Massachusetts Survey of Beliefs, Knowledge about AIDS HIV and Behavior

1) *Susceptibility*
- How much do you worry that you could get AIDS in your lifetime? (A great deal, Some, A little, Not at all.)
- How likely is it that if a man and woman have sex, and the man is infected with HIV, that the woman will become infected? (Very, Somewhat, A little, Not at all.)
- How likely is it, if the woman is infected, the man will become infected? (Very, Somewhat, A little, Not at all.)
- If two men have sex and one is infected how likely is it the other will become infected? (Very, Somewhat, A little, No at all.)

2) *Severity*
- Is there a cure for AIDS? (Yes, No)
- How likely is it that someone with AIDS will die from the disease? (Very, Somewhat, A little, Not at all.)

3) *Effectiveness*
- How effective are condoms in preventing transmission of AIDS virus? (Extremely, Very, A little, No at all effective.)

4) *Barriers to Action*
- How true do you think it is that:
  - condoms are difficult and embarrassing to obtain (Very, Somewhat, A little, Not at all)
  - condoms reduce pleasure (Very, Somewhat, A little, Not at all)
- If your partner wanted a condom to be used during intercourse, how likely is it that:
  - you would be embarrassed (Very, Somewhat, A little, Not at all)
  - you would be upset with your partner (Very, Somewhat, A little, Not at all)

- Do you usually carry condoms with you? (Yes, No)

5) *Cues to Action*

- Did you read or hear anything about AIDS, in the past week, in the newspaper, magazine, radio, or T.V.? (Yes, No)
- Have you ever discussed AIDS with a parent or other adult member of your family? (Yes, No)
- Have any of your teachers in school every talked about AIDS? (Yes, No)
- Have you ever discussed AIDS with a physician (Yes, No)
- Do you know anyone with AIDS? (Yes, No)

AAFP and CDC Recommend Second MMR Vaccination at Preschool Age

The American Academy of Family Physicians (AAFP) recommends routine second measles, mumps and rubella (MMR) immunizations for children four to six years of age, or just prior to entering school. The national association representing more than 68,000 family doctors, residents, and medical students also said that children in areas where there is a high risk of contracting measles should receive their first MMR at 12 months, instead of 15 months of age. The revised guidelines calling for two childhood measles vaccinations concur with the Immunizations Practice Advisory Committee's report: *Measles Prevention*, issued recently by the federal Centers for Disease Control (CDC). The AAFP revised its schedule for MMR vaccinations because of the increasing number of infants, children and adolescents who have contracted measles. About five out of every 100 children previously immunized failed to develop protection against measles.

The new guidelines define a high-risk area as a county or portion of a county with:

- more than five measles cases among preschool-aged children during each of the last five years;
- a recent outbreak among unvaccinated preschool-aged children; or
- a large urban population.

CDC also recommends a second MMR shot or a measles immunity test for everyone who is going to college or other educational institutions beyond college, as well as medical personnel beginning employment who will have direct patient care contact.

Persons who are *not recommended* to receive a measles vaccination generally include pregnant women, persons with active tuberculosis, or those who have allergies to eggs.

The Growing Proportion of Female Physicians: Implications for US Physician Supply

PHILLIP R. KLETKE, PHD, WILLIAM D. MARDER, AM, AND ANNE B. SILBERGER, AM

Abstract: This study analyzes how the growing proportion of women in the United States physician population will affect the amount and type of physician services available to the US population. Female physicians work fewer hours per week, are slightly less likely to be in patient care, and tend to enter different specialties than male physicians. Female physicians also have higher retirement rates than male physicians, but due to their lower mortality rates, have work lives nearly as long as male physicians. We examined how the changing composition of the physician population will affect the availability of physician services by comparing historical and projected trends for the number of active post-residency physicians with comparable trends for a full-time-equivalent measure of physician supply. The full-time-equivalent measure takes into account the different labor supply behavior of key subpopulations (e.g., women and graduates of US versus foreign medical schools). The results suggest that the changing composition of the physician population will reduce the growth of effective physician supply between 1986 and 2010 but only by four percentage points. (*Am J Public Health* 1990; 80:300–304.)

Introduction

The proportion of United States physicians who are women has grown rapidly since 1970 and, according to recent projections,[1] it will continue to rise until the year 2010. Since the practice characteristics of female physicians differ from those of male physicians, the growing representation of women in the medical profession is likely to have significant effects on the future supply of physicians.

In general, women physicians have been disproportionately represented in pediatrics and psychiatry and have been underrepresented in the surgical specialties.[2,3] Analyses of the most recent cohorts of new physicians, however, show that the specialty distributions of male and female physicians appear to be converging.[4] This convergence is much more pronounced among graduates of US medical schools (USMGs) than graduates of foreign medical schools (FMGs).[5] Nevertheless, there are still significant differences in the specialty choices of male and female US medical students.[6]

Numerous studies have documented that female physicians work fewer hours per week than male physicians,[7–11] and several analyses have explored the extent to which this difference is attributable to marital status and household responsibilities.[12,13] Longitudinal data show that the differences in the number of hours male and female physicians work may be decreasing, although significant differences still remain.[14] Because women physicians work fewer hours per week than male physicians and are comprising an increasing proportion of the physician population, some analysts have concluded that current projections of the physician population overstate effective future physician supply.[15,16] Partly in response to this issue, a recent report of the US Council on Graduate Medical Education[17] indicated that the practice patterns of male and female physicians deserve greater research. This paper measures current differences between male and female physicians and traces their consequences for future physician supply.

Methods

We used the Physician Masterfile[2] of the American Medical Association (AMA) for both current and historical data on all US physicians (both AMA members and nonmembers). We used the Demographic Model of the Physician Population[1] to project the size and composition of the future physician population.

Our projection of the physician population assumed that:

- the proportion of women among graduates of US medical schools will increase 1 percent per year from 32 percent in 1986 until it reaches 40 percent and will remain constant thereafter;
- male and female physicians will choose specialties following patterns identical to the most recent cohorts of medical school graduates; and
- retirement and mortality rates for male and female physicians will remain constant at their current levels.

We analyzed data from the AMA Socioeconomic Monitoring System[11] to examine practice differences of male and female physicians. These data come from a series of periodic telephone surveys of random samples of non-federal, postresident, patient care physicians since 1982. We used data from the 1987 core survey, which has data on approximately 4,000 physicians.

Results

Demographic Characteristics

Table 1 shows that the proportion of women physicians increased from 7.1 percent to 15.3 percent between 1970 and 1986, and is projected to reach almost 30 percent by the year 2010. Consequently, women physicians are concentrated in the younger age categories. In 1970 and 1986, female physicians were disproportionately represented among foreign medical graduates not born in the US, but the relationship between sex and country of graduation reverses during the projection period due to the growing number of females graduating from US medical schools. Female physicians are concentrated in pediatrics and psychiatry and are underrepresented in general surgery and the surgical subspecial-

ties. These patterns appear in both the 1970 and 1986 data as well as the projection estimates for 2000 and 2010.

Differences in the specialty distributions of male and female physicians persist but are gradually weakening, however. The index of dissimilarity for the specialty distributions of male and female post-resident physicians (i.e., the percent of female physicians who would have to change specialties so that their specialty distribution would match that of male physicians) dropped from 31.2 to 23.7 between 1970 and 1986, indicating that the concentration of female physicians in certain specialties has decreased. The index calculated only for physicians less than 35 years of age dropped from 28.5 to 18.4 during the same period.

The mortality, retirement, and accession (resumption of activity) rates for the projection model were estimated from an analysis of Masterfile data for years 1978 to 1986 from a set of logistic regression equations, based on the physician's age, sex, specialty, and country of graduation. (Analyses available on request to author.) Female physicians had higher retirement rates and lower mortality rates than male physicians. By assuming that the schedules of transition rates remain constant, we estimated how much longer physicians of a given age, sex, specialty, and country of graduation are, on average, likely to live, and how much longer they are likely to be professionally active.

Table 2 presents the expected years of remaining life and the expected years of remaining work life for active male and female USMG physicians at ages 35, 50, and 65 in 13 different specialty groups. Physicians on average, live and work longer than the rest of the US population. Female physicians can expect to live approximately four to five years longer than male physicians, but their higher retirement rates mean that

active female physicians at age 35 have approximately the same expected work life as male physicians at 35.

Physician Time in Patient Care

Among the entire post-residency physician population, 89.7 percent of male physicians and 88.0 percent of female physicians are classified as being in direct patient care (i.e., spending the plurality of their professional working hours treating patients in either an office-based or hospital-based practice). The proportion decreases somewhat for older physicians, and both USFMGs and foreign-born FMGs are slightly more likely than USMGs to be in patient care. (Data available upon request to author.) The probability of being in patient care was highest in general/family practice, the surgical subspecialties, and obstetrics/gynecology, and lowest in the medical subspecialties, pathology, and in the residual "other specialties" category. There are few differences by gender.

Table 3 shows that post-residency patient care physicians worked an average of 58.3 hours per week in 1987. On average, female physicians, older physicians and USMGs worked fewer hours than their counterparts. Physicians in general internal medicine, the medical subspecialties, pediatrics, obstetrics/gynecology, and emergency medicine worked several more hours per week than average, while physicians in psychiatry, pathology, and the other specialties worked fewer hours than average.

SOURCE: Marder, *et al. Physician Supply and Utilization by Specialty: Trends and Projections.* Table 2.6, p.18.

The findings reported for the proportion of physicians in patient care and their average hours of work per week were confirmed in a logistic regression analysis of whether a physician was in patient care and an ordinary least squares regression analysis of the log of hours worked per week by patient care physicians. (Analysis available on request to author.) Independent variables were: the physician's sex, country of graduation, specialty, physician's age and age-squared (since the relationships with the dependent variables did not appear to be linear with respect to age), and interaction terms for sex with age and age-squared.

In each analysis, the coefficients for sex and the age-sex interactions were jointly significant at the .001 level. Plots of the age-specific regression estimates for male and female physicians indicated that female physicians are slightly less likely to be in patient care than male physicians for all ages. The hours worked per week by patient care physicians peak at age 37 for male physicians and at age 43 for female physicians. Male physicians generally work more hours than female physicians, but the differential decreases with age.

Alternate Measures of Physician Supply

Some researchers have speculated that because female physicians work fewer hours per week than male physicians and because the proportion of female physicians is increasing, projections of the total physician population may overestimate effective physician supply. We investigated this issue by estimating the *aggregate time worked by patient care physicians*, measured in terms of full-time-equivalent physicians. This measure includes only physicians in direct patient care and weights each physician with the amount of time spent in professional activities. This adjusted measure of physician supply takes into account the changing composition of the physician population. We compared this measure of the effective physician supply with the simple number of physicians.

We considered the population of post-resident physicians—physicians who have completed specialty training—because we wanted to analyze how the changing composition of physician supply will affect the specialty distribution of physician services. Our projection estimates did not indicate how many physicians have completed residency training, so we estimated the future number of post-resident physicians based on the available information—the projected age, sex, country of graduation, and specialty distributions of the future physician population. We used a logistic regression analysis of the 1986 AMA Physician Masterfile data to estimate $q_{i,j,k,l}$, the proportion of physicians of age i, sex j, specialty k, and country of graduation l who have completed residency training. (Analyses available upon request to author.) Assuming that these proportions remain constant throughout the projection, we estimated P, the projected size of the active post-resident physician population, as follows:

$$P = \sum P_{i,j,k,l}$$

$$= \sum [q_{i,j,k,l} A_{i,j,k,l}]$$

where $A_{i,j,k,l}$ represents the projected number of active physicians in the corresponding age-sex-specialty-country of graduation category.

We estimated F, the future number of full-time equivalent patient care physicians, as follows:

$$F = \sum F_{i,j,k,l}$$

$$= \sum \left[c_{i,j,k,l} h_{i,j,k,l} P_{i,j,k,l} \frac{1}{58.0} \right]$$

where $c_{i,j,k,l}$ is the estimated proportion of physicians in each sex-age-specialty-country of graduation category who are in patient care, derived from our logistic regression analysis of the 1986 Masterfile data; $h_{i,j,k,l}$ is the estimated number of hours worked by patient care physicians, derived from the ordinary least squares analysis of the SMS data; and 58.0 is the average hours per week worked by patient care physicians in 1987.

Table 4 presents historical and projected data for the number of active post-residency physicians, and the number of full-time-equivalent post-residency patient care physicians. Both measures show that physician supply is growing rapidly. Projected growth is slightly slower for the full-time-equivalent measure.

The bottom line of Table 5 presents the number of full-time-equivalent patient care post-residency physicians divided by the total number of post-residency physicians. This ratio describes how effectively the projected physician population will provide time to patient care in terms of 1986 full-time-equivalent patient care physicians. During the 1970–86 historical period, the ratio increased slightly from .888 to .896. Despite the growing proportion of female physicians throughout this time period, the average physician provided more patient care because: the proportion of patient care physicians increased; and a greater proportion of physicians were entering the middle parts of their careers, during which they provide the most patient care.

Between 1986 and 2010, the ratio is projected to decrease from .896 to .854, representing more than a 4 percent

TABLE 4—The Number of Active Post-residency Physicians and the Number of Full-Time-Equivalent Post-residency Patient Care Physicians by Age, Specialty, and Country of Graduation, for Years 1970, 1986, 2000, and 2010

	Historical		Projected	
	1970	1986	2000	2010
Active Post-residency Physicians	262,694	438,935	567,300	611,100
Full-Time-Equivalent Post-residency Patient Care Physicians	233,400	393,500	495,700	522,100
Ratio of Full-Time-Equivalent Post-residency Patient Care Physicians to Active Post-residency Physicians	888	896	873	854

SOURCE: AMA Physician Masterfile, 1970–86, Department of Data Release Services, Division of Survey and Data Resources, AMA Demographic Model of the Physician Population, AMA Center for Health Policy Research, 1988.

decrease in the amount of patient care provided by the average physician. This finding is attributable to the growing proportion of women physicians who, on average, work fewer hours per week and are somewhat less likely to be in patient care; and to the growing proportion of older physicians, who work fewer hours per week.

Table 5 shows the percent growth in the two supply measures for the various components of the physician population in 1970–86 and 1986–2010. Both measures indicate that the physician population is growing rapidly, although the growth rate is gradually diminishing. Both indicate that: the percent growth is substantially larger for female physicians than for male physicians; growth rates for emergency medicine, general internal medicine, and pediatrics are greater than for other specialties; and the number of physicians over age 65 will grow faster than the physician population as a whole.

More important for this analysis are the subtle differences between the two measures attributable to changes in the composition of the physician population. In both time periods, the percent increase of active post-residency physicians is several percentage points greater than their full-time equivalents, i.e., the growth of the physician population is slightly faster than the growth of effective physician supply.

For almost all the components of the physician population, the percent increase in active physicians exceeds the percent increase in full-time-equivalent patient care physicians. Female physicians are an important exception. Between 1986 and 2000, disproportionate numbers of female physicians will enter the middle age categories when they spend the most time in patient care. On the other hand, male physicians will be entering the older age categories and thus are expected to work fewer hours per week. Due to this difference, the sex differential in the rate at which physicians provide patient care will decrease in the future.

Discussion

If current patterns persist, the rapidly growing proportion of female physicians will affect both the amount and type of health care available in the future. We have presented data

TABLE 5—Percent Change in the Number of Active Post-residency Physicians and the Number of Full-Time-Equivalent Post-residency Patient Care Physicians, 1986–2000 and 1986–2010

	Percent Change in Post-residency Population

on several important past differences between male and female physicians. The projected growth of the physician population slightly overstates projected growth in the effective supply of physician hours worked. However, the actual magnitude of this difference is small, especially when compared to the rapid growth projected for the physician population.

It is quite likely that, as the number of female physicians increases over time, their practices will more closely resemble those of male physicians. Several factors suggest that some of the differences between male and female physicians may be declining. The specialty distributions of male and female physicians appear to be becoming more similar, especially among the younger age groups. Female physicians are no longer disproportionately represented among foreign-born FMGs. Even though female physicians have higher retirement rates than male physicians, their expected work lives are just as long as male physicians due to their lower mortality rates. As career patterns of male and female physicians become more similar, the classic measures of physician supply will be more reliable indicators of long-term growth.

New Quarterly Periodical: *Accountability in Research*

A new quarterly journal, entitled *Accountability in Research: Policies and Quality Assurance*, was launched in September 1989 to serve as a forum for critical examination of issues involving the integrity of scientific data. The papers appearing in the first issue are based, in part, on presentations from the First International Conference on Scientific Data Audit, Policies, and Quality Assurance held May 8–10, 1988 at the University of Maryland, College Park. Adil E. Shamoo, University of Maryland School of Medicine, has been named Editor-in-Chief of the new journal.

According to "A Note from the Editor" in the inaugural issue, "Researchers today perceive a growing problem of error and fraud in the vast research and development enterprise. The growing complexity of research, the increased distance between those who gather, manipulate, and evaluate data, and the mounting financial and professional pressures on researchers all contribute to this problem. In recent years, the need for a broad-based consensus on ways of ensuring the integrity of scientific data has become increasingly clear," Shamoo wrote.

The journal will speak to a broad, interdisciplinary range of scientists and administrators in academia, industry, and government. "While relevant to many disciplines," he said, "it will focus in particular on biotechnology, chemistry, medicine, pharmacology, toxicology, pathology, and environmental science. Topics to be addressed include: historical perspectives on data integrity; auditing data as a management tool; research policies and their impact on science and the public; ethical and legal issues; relevant data analysis methods and technology; and legislative and regulatory aspects."

The journal welcomes divergent views on these and related topics from research scientists as well as those in the fields of accounting, law, economics, statistics, management studies, public policy, and information science.

Submissions to the journal should be sent in triplicate to the Editor-in-Chief, Adil E. Shamoo, Department of Biological Chemistry, University of Maryland School of Medicine, 660 West Redwood Street, Baltimore, MD 21201.

Subscription rates and other information or **a sample copy** may be obtained from the publisher: Gordon and Breach, Science Publishers, Marketing Department, P.O. Box 786 Cooper Station, New York, NY 10276, USA; or P.O. Box 197, London WC2E 9PX, UK.

Cryptosporidium Infection in Oregon Public Health Clinic Patients 1985–88: The Value of Statewide Laboratory Surveillance

MICHAEL R. SKEELS, PHD, MPH, ROBERT SOKOLOW, BS, MBA, C. VANCE HUBBARD, BS, M(ASCP), JON K. ANDRUS, MD, AND JOANNE BAISCH, RN

Abstract: To evaluate the utility of statewide laboratory *Cryptosporidium* surveillance, we screened stools from all 5,256 patients evaluated at local health departments for parasitic disease from January 1985 through June 1988. Fifty-seven patients (1.1 percent) were found to have *Cryptosporidium*. Seasonal peaks in positivity were observed in the spring, summer, and early autumn months. In children, younger age was associated with higher positivity rate of cryptosporidiosis. As a result of these surveillance efforts, Oregon's first known outbreak of cryptosporidiosis was detected and investigated during 1988. Twenty-five persons were infected, including children, parents, and staff associated with two day care centers. The cost of routine screening for *Cryptosporidium* was $1.13 per specimen in our laboratory, and we consider it useful. (*Am J Public Health* 1990; 80:305–308.)

Introduction

With reports from at least 26 countries,[1–4] *Cryptosporidium* is now well recognized as a pathogen in immunocompetent patients seen for diarrheal disease in a variety of clinical settings. In the United States, most cases are derived from a continuous human reservoir sustained by fecal-oral transmission, with occasional zoonotic infections acquired from cattle, goats, lambs, and domestic animals.[5,6] Surface water may also be an important source of infection.[7,8] Several outbreaks have been reported in day care centers.[9–11] The prevalence of human cryptosporidiosis differs greatly between geographic areas, even within the United States,[12,13] and there is also some evidence for seasonal fluctuation.[14–16]

Many laboratories are currently considering the addition of *Cryptosporidium* screening to the battery of routine tests used for all stools submitted for parasitology. Although *Cryptosporidium* screening is relatively simple, it requires unique staining and examination apart from the usual methods, and its implementation raises issues of cost and work flow which must be addressed. Its usefulness depends upon several factors, including the local prevalence of the agent, the potential for transmission in the population screened, and the cost of screening. There is little information available to assist laboratories and disease control programs in deciding whether to adopt *Cryptosporidium* testing as a part of their routine parasitology protocol.

We have been screening for *Cryptosporidium* infection in immunocompetent public health clinic patients since 1984, and have previously reported our findings in 1,710 patients from our initial year of study.[12] In that report, we noted that although Oregon had not yet experienced the cryptosporidial positivity rate observed in some other areas, we did plan to continue active surveillance. Our ongoing screening during the ensuing three-and-one-half years has allowed us to define further the positivity rate in a selected population, and to detect the first known outbreak of cryptosporidiosis in Oregon. In addition, we have continued to examine the putative association between *Giardia* and *Cryptosporidium* which has been reported by others.[17,18]

Methods

From January 1, 1985 through June 30, 1988, all stool specimens submitted to the Oregon State Public Health Laboratory for parasitological examination from local health department clinics were screened for *Cryptosporidium* in addition to *Giardia* and other parasites. These specimens, which were collected from persons evaluated for parasitic gastroenteritis, were submitted from all of Oregon's local health department outpatient clinics.

All stools were received in 10 percent formalin and concentrated by the formalin-ethyl acetate method.[19] Iodine stained and unstained preparations were examined at both low (100×) and high (400×) magnification for parasitic forms other than *Cryptosporidium*. A smear from each sample was then stained and examined for *Cryptosporidium* in the manner which we have described previously.[12] Briefly, each smear was stained by the auramine-O fluorochrome method and scanned at 400× magnification using a fluorescence microscope with a 390-490 nm light source. Smears were considered presumptively positive if at least one fluorescing object of correct size (and any morphology) was observed per field, or if fluorescing objects morphologically typical of *Cryptosporidium* were observed in any number. *Cryptosporidium* oocysts were seen as typical rings or crescent forms with a mean diameter of 4.5 μm and a resemblance to crenated erythrocytes. Each presumptively positive smear was then overstained with our modification of the Ziehl-Neelsen (Z-N) method for confirmation. The combination of formalin-ethyl acetate concentration plus acid-fast staining has been found to be equivalent to the Sheather sucrose method for recovery of cryptosporidial oocysts.[20] After Z-N staining, the sample was examined at 1,000× magnification and considered confirmed positive if acid-fast oocysts with typical morphology were observed. Positive and negative controls were included in each run and examined in the same manner as clinical specimens. Proper control reactions were a prerequisite for accepting and reporting the concurrent patient results; these controls were correct in 100 percent of the test runs.

Results

Laboratory Surveillance

A total of 5,256 patients (8,396 specimens) were screened for *Cryptosporidium* and other parasites; the percentage who

had diarrhea was unknown to us. The patients were drawn from a variety of ethnic backgrounds and locales throughout Oregon. Fifteen percent (786) had Southeast Asian surnames; none of these patients were positive for *Cryptosporidium*. Only one of the positive patients was known to have human immunodeficiency virus infection. The age distribution of patients is shown in Table 1.

Fifty-seven of the patients screened (1.1 percent) had stools positive for *Cryptosporidium*, although 25 of these patients were related to the day care-associated outbreak in 1988. Eight of 666 patients with *Giardia* (1.2 percent) had *Cryptosporidium*, compared with 49 of 4,590 patients (1.1 percent) who did not have *Giardia*.

Excluding specimens from the patients who were tested as part of our 1988 outbreak investigation (25 positive and eight negative), the three-and-one-half year statewide "background" *Cryptosporidium* positivity rate among those persons screened was 32 of 5,223, or 0.61 percent. The proportion positive for each age group is given in Table 1. When we compared proportion positive by one-year age increments, we found that among patients less than 18 years old who were tested, younger children were more likely to be infected with *Cryptosporidium*; however, the numbers were small and this difference did not reach statistical significance ($p = .07$, chi-square analysis for trend).

Cryptosporidiosis Outbreak, 1988

As a result of laboratory surveillance, Oregon's first known community outbreak of cryptosporidiosis that occurred during a 10-week period from mid-April through June 1988 was discovered and investigated. A total of 24 cases and one asymptomatic infection were identified in two day care centers in one community in western Oregon. Cases were defined as having a diarrheal illness with laboratory confirmation of the presence of *Cryptosporidium* oocysts in stool specimens. The epidemic curves by day care center for this outbreak are consistent with initial person-to-person transmission of infection, perhaps followed by a common source outbreak (Figure 1).

The outbreak was brought to the attention of the local health department in the following manner. A child attending Day Care B was found to be positive for *Giardia* and negative for *Cryptosporidium*; however, an investigation revealed that the child had two infant siblings attending Day Care A. One of the two siblings had a stool sample positive for both *Cryptosporidium* and *Giardia*, and the stool sample from the other was negative for both agents. The finding by the laboratory of *Cryptosporidium*, which had not been suspected in this outbreak, alerted the local health department to the need to conduct an epidemiologic investigation centered on this organism.

TABLE 1—*Cryptosporidium* Positivity Rate in Oregon Public Health Patients by Age, 1985–88

Age (years)	No. Patients Examined	% Positive		
		Day Care Outbreak*	Other	Total
<1	188	66.7 (2/3)	1.1 (2/185)	2.1
1–4	1,248	76.5 (13/17)	1.3 (16/1,231)	2.3
5–9	671	100.0 (2/2)	0.6 (4/669)	0.9
10–14	273	100.0 (2/2)	1.1 (3/271)	1.8
15–17	139	0 (0/0)	0 (0/139)	0
≥18	2,540	66.7 (6/9)	0.2 (6/2,531)	0.5
Unknown	197	0 (0/0)	0.5 (1/197)	0.5

*Outbreak April–June, 1988.

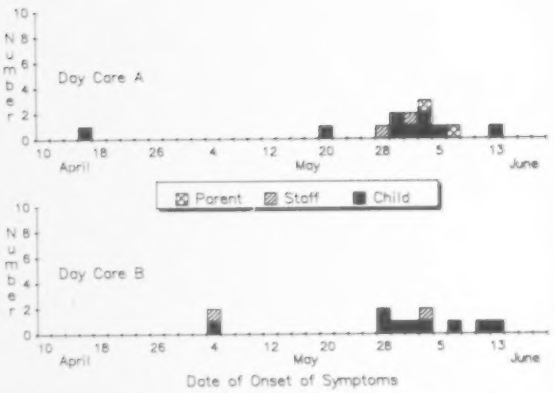

FIGURE 1—Epidemic Curves for Oregon Cryptosporidiosis Outbreak, 1988

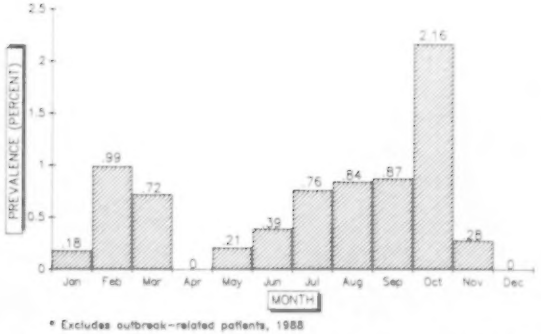
The cryptosporidiosis attack rate for attendees at Day Care A was 90 percent (9/10 children attendees). The onset of the initial case occurred in mid-April. The average age of the children-cases was 1.8 years with a range from 0.8 to 6.0 years. One of the nine case-children also had *Giardia* on stool examination. Both adult staff at Day Care A were infected with *Cryptosporidium*. In addition, two parents of attendees were reported as cases.

At Day Care B the cryptosporidiosis attack rate for attendees was 60 percent (9/15 children). The date of onset of the initial case was May 5, 1988. One attendee had a positive stool specimen, but was asymptomatic, and therefore was not counted as an outbreak-related case. The average age of the case-children was 3.7 years with a range of 2.5 to 6.0 years. Two of the nine case-children also had *Giardia* on stool examination, as did one of the six children who were negative for *Cryptosporidium*. This child was also infected with *Entamoeba histolytica* and *Blastocystis hominis*. In addition to these attendee cases, two of six adult staff were cases. None of the parents were reported as cases.

Excluding the three cases with concurrent giardiasis, who received antimicrobic therapy, all other cases had self-limiting illnesses without treatment; however, the clinical course of one adult case was complicated by a 12-pound weight loss. Among the 10 cases for whom information was available, the average duration of symptoms was eight days with a range of one to 28 days. No one required hospitalization. Control measures included strict handwashing technique and environmental sanitation measures such as cleaning of toys; however, cohorting was not implemented. During the first week of July 1988, repeat stool examinations of all children attendees and infected adults were negative for cryptosporidiosis.

Seasonal Fluctuations in Positivity Rate

When our data were aggregated by month for January 1985 through June 1988, with the 1988 outbreak patients excluded, peak positivity rates were observed in February/March and in summer and early autumn (Figure 2). Given the small number of positive stools in each year, it was necessary to combine the data in this way to identify seasonal patterns.



* Excludes outbreak-related patients, 1988

FIGURE 2—*Cryptosporidium* Prevalence in 6,223 Oregon Public Health Patients Screened for Ova and Parasites by Month, January 1985–June 1988*

Discussion

In Oregon, our finding of 0.61 percent "background" positivity rate in patients screened at all local health department clinics during 1985–88 is consistent with our previous report of 0.35 percent for the same population during 1984.[12] Combining all data for both time periods, including the 1988 outbreak, we have screened 6,966 patients and found 63 (0.90 percent) to be positive for *Cryptosporidium* during four-and-one-half years. Although positivity rates of *Cryptosporidium* vary widely by geography, setting, and population, our results are similar to those reported from Colorado, Texas, Ohio, and British Columbia.[6,13,16,21]

Young children had the highest positivity rate of cryptosporidial infection in our study, even when patients from the 1988 day care-associated outbreak were excluded from the analysis. This finding is consistent with those of other workers and is generally attributed to either greater susceptibility in children or to more efficient fecal-oral transmission among infants and toddlers.[5,16] Less obvious is the source of cryptosporidiosis in older children and adults, many of whom present as sporadic cases without a known source of infection. Many may acquire their infection through contact with young children, as has been suggested in other outbreak situations involving both adults and children.[5,7,11] However, the importance of adult-to-adult transmission (in the immunocompetent) and environmental acquisition is unknown.

Although our findings did not reveal a "statistically significant" association between *Giardia* and *Cryptosporidium* in the population screened or among the day care outbreak cases, co-transmission of these two agents and others may be common during outbreaks. Information is lacking regarding the sensitivity of a single stool examination for the detection of coinfection by these agents. Thus, because of intermittent cyst shedding, differences in incubation period between the two protozoa, the timing of any given sample, and differences in the sensitivity of the laboratory methods, it is possible for one of the pathogens to go undetected, even in a dual infection. For example, some patients excrete atypical *Cryptosporidium* oocysts which are quite fragile and sometimes cannot be stained by the usual methods.[22] Seasonal fluctuations in cryptosporidiosis have also been reported from other countries. Peak prevalences during the late summer and early autumn months have been reported from England[23,24] and Australia;[25] two other studies from the United Kingdom showed peaks during the spring months.[14,15] Among all the seasonal cryptosporidiosis data which are available, those from British Columbia may be the most useful for comparison to our results in Oregon, given the environmental, geographic, and demographic similarities between the two areas. In a one-year study of 7,300 patients with diarrhea in the Vancouver area, the peak incidence was seen in August and September, with over half of the cases occurring in those two months.[16] Our seasonal findings are consistent with those from the Untied Kingdom, Australia, and British Columbia. The interpretation of this seasonality is unclear, but could reflect changing opportunities for acquisition of infection from the environment (e.g., travel, contact with surface water or animals), or for person-to-person transmission.

The relative importance of environmental versus person-to-person transmission of *Cryptosporidium* is still poorly defined, and a better understanding is central to the development of control measures for this agent. Using our experience with *Giardia* as a model, we know that over one-fourth of Oregon giardiasis cases are attributed to drinking surface water, and that there have been several documented community drinking water supply outbreaks of giardiasis in Oregon during the past decade.* There may exist a background of ongoing person-to-person *Giardia* transmission, especially among young children, perhaps augmented by frequent acquisition of the organism from contaminated surface water. Such a pattern may also exist for cryptosporidiosis, but until recently the available technology has limited our ability to examine water for cryptosporidial oocysts.

At least two US waterborne community outbreaks of cryptosporidiosis have been documented, in Texas and Georgia,[26,27] and very recently, the drinking of surface water was identified as an important risk factor in *Cryptosporidium* infections in New Mexico.[7] The Georgia outbreak arose from a sand-filtered and chlorinated community water supply which met all regulatory standards. The presence of cryptosporidial cysts was attributed to infected cattle in the watershed; inadequate flocculation filtration may have allowed the organism to contaminate the drinking water system. Within the past four years, methods have become available for identifying cryptosporidial oocysts in water.[8,28] In Arizona, a study of surface waters during summer 1986 revealed widespread stream contamination with *Cryptosporidium*.[29] A midsummer study of four rivers in Washington and two in northern California showed all six to be contaminated with cryptosporidial oocysts.[8] Similar contamination in nearby watersheds in Oregon seems plausible, especially given the similarities in geography and potential for contamination by dairy cattle and other animals. Comparable studies of Oregon surface water are needed.

An important question about routine cryptosporidial screening of stool samples is whether the cost is justified by the yield. In our laboratory, the direct materials and labor cost for the inclusion of *Cryptosporidium* screening into the usual ova and parasite examination is an additional $1.13 per specimen ($1.03 for personnel, $.10 in materials). The cost-effectiveness of this screening in a given locale will depend

*Oregon disease surveillance reporting data, unpublished. Portland: Oregon Health Division, 1989.

upon the individual laboratory cost, the local prevalence of *Cryptosporidium* and the capacity for preventing and controlling outbreaks once infected persons have been identified.

We conclude that laboratory-based surveillance is useful in defining the *Cryptosporidium* positivity rate and patterns of transmission for a given locale, and in detecting outbreaks when they occur. In areas where *Cryptosporidium* screening is not routinely performed, it is possible that the etiology of diarrheal outbreaks, particularly among children, may remain undiscovered or may be incorrectly attributed to other agents. Even in low prevalence populations, laboratory-based surveillance may be justified due to the relatively low cost of screening and the potential for early intervention in outbreaks.

Call for Abstracts on Dental Public Health Topics

The American Association of Public Health Dentistry has issued a call for abstracts of papers on a broad range of dental public health topics for presentation at its 53rd annual meeting, to be held in Boston, Massachusetts October 10–13, 1990. The theme for the meeting is "Health for All: Opportunities and Responsibilities for Dental Public Health."

Major topics being sought include: access to services, trends in oral diseases or conditions, preventive and educational measures, national/state/local dental programs, delivery systems, infection control, ethics, and impact of state practice acts.

The *deadline for submission of abstracts is April 1, 1990*. An abstract form and information can be found in the November 1989 issue of *Communique* (AAPHD's newsletter) and the Winter 1990 issue of the *Journal of Public Health Dentistry*. Send abstracts to: Alice M. Horowitz, RDH, MA, AAPHD Vice President, 6307 Herkos Court, Bethesda, MD 20817.

For further information, contact AAPHD National Office, 10619 Jousting Lane, Richmond, VA 23235. Tel: 804/272-8344.

A Comparison of Alcohol Sales Data with Survey Data on Self-Reported Alcohol Use in 21 States

PERRY F. SMITH, MD, PATRICK L. REMINGTON, MD, MPH, DAVID F. WILLIAMSON, PHD, AND ROBERT F. ANDA, MD

Abstract: We used data from 21 states that participated in the 1985 Behavioral Risk Factor Surveillance System to compare state-specific per capita self-reported alcohol consumption and the prevalence of three drinking behaviors with state-specific per capita sales. The correlation coefficient for per capita sales and per capita self-reported consumption for the 21 states was 0.81. Per capita sales were also significantly correlated with the prevalence of self-reported heavier drinking, binge drinking, and drinking and driving; the corresponding correlation coefficients were 0.74, 0.59, and 0.51. These findings suggest that states with higher per capita sales of alcohol also have higher rates of self-reported consumption and drinking patterns suggestive of high-risk behavior. (*Am J Public Health* 1990; 80:309–312.)

Introduction

The social, medical, and economic costs of alcohol abuse are a major public health problem in the United States.[1] At the state level, public health officials are paying increased attention to the consequences of problem drinking. Recently, investigators estimated that problem drinking in Minnesota accounted for 1,110 deaths and for $1.4 to $2.1 billion in medical and social expenditures during 1983.[2]

Because direct measures of problem drinking are not always available, indirect measures, such as total sales, are often used to estimate the total alcohol exposure for state populations. For example, one of the 1990 health objectives for the nation is to limit per capita consumption of alcohol to 2.71 gallons per year, an amount estimated from alcohol sales.[3] Sales data at the state level may mismeasure actual per capita consumption because of out-of-state visitors' purchase of alcohol and wastage or stockpiling of alcohol.[4] More importantly, per capita sales may not reflect rates of problem drinking in a population.[5]

A somewhat more direct method for estimating alcohol exposure at the state level is the use of survey data of self-reported alcohol consumption by individuals. However, survey data may not accurately reflect rates of problem drinking for various reasons, including biased self-reporting and problems with sampling.[4,6–8]

Although public health officials use alcohol sales as a measure of typical alcohol consumption and of the frequency of problem drinking, it has not been shown that states with higher alcohol sales have higher levels of per capita consumption and/or higher frequency of drinking behaviors that increase a person's risk for alcohol-related morbidity and mortality. A strong correlation between sales and survey data at the state level would support the use of sales information for monitoring alcohol consumption. To determine the strength of this correlation, we compared state-specific per capita alcohol sales with rates of per capita consumption and three drinking behaviors as reported in surveys administered in 21 states in 1985.

Methods

We obtained state-specific estimates of per capita alcohol sales for 1985 from the Alcohol Epidemiologic Data System of the National Institute on Alcohol Abuse and Alcoholism (NIAAA).[9] These data are based on beverage sales and tax receipt figures for states in which these data are available (including 13 of the 21 states in our study). For the remaining states, data are used on product shipments from major alcoholic beverage industry sources (the Distilled Spirits Council of the United States, United States Brewers Association, and the Wine Institute). For this report, we refer to both sources of data as "alcohol sales." Per capita alcohol sales are determined by dividing each state's total sales in gallons of absolute alcohol for beer, wine, and liquor by the number of state residents aged 14 years and older.

To estimate state-specific rates of alcohol consumption and drinking behaviors based on self-reports, we used 1985 data from the Behavioral Risk Factor Surveillance System. This system uses random-digit telephone surveys for the state-level surveillance of behaviors related to the leading causes of death among adults in the United States. Described in detail elsewhere,[10] the methodology is briefly summarized here.

In 1985, 21 states participated in the surveillance system. Adult respondents were randomly selected from civilian residents, aged 18 years or older, who had telephones. The sample was chosen by a multistage cluster design procedure based on the Waksberg method.[11] Trained interviewers in each state conducted interviews by telephone; calls were made during the day, at night, and on weekends and lasted about 15 minutes each.

In each state, about 100 interviews were completed each month; the annual total per state ranged from 628 to 2,386 (median = 1,177) (Table 1). Response rates were calculated as the percentage of eligible respondents contacted who completed interviews, and ranged from 61–92 percent (median = 83 percent), among the 19 states for which this information was available.

Respondents were asked to report their beer, wine, and liquor consumption, including the number of days in the prior month that they had consumed each type of beverage and the average number of drinks they had consumed per day. They were also asked two questions: "Considering all types of alcoholic beverages, that is, beer, wine, and liquor, as drinks, how many times during the past month did you have five or more drinks on an occasion?" and "During the past month, how many times have you driven when you've had *perhaps* too much to drink?" Those who did not report consuming any alcohol in the month before the interview were considered nondrinkers. For the 21 states, the percentage of nondrinkers ranged from twenty-six to sixty-nine percent (median = forty-one percent) (Table 1).

Smith, MD, Bureau of Communicable Disease Control, New York State Department of Health, Empire State Plaza, Corning Tower Building, Room 678, Albany, NY 12237. This paper, submitted to the Journal November 21, 1988, was revised and accepted for publication July 31, 1989.

TABLE 1—Number of Completed Interviews, Response Rates, and Percentage Nondrinkers, by State, Behavioral Risk Factor Surveillance System, 1985

State	No. of Completed Interviews	% Response Rate*	Percentage Nondrinkers**
Arizona	1,175	76.5	41.0
California	1,372	82.6	37.3
Connecticut	983	***	30.3
Florida	818	61.2	40.4
Georgia	818	81.8	53.8
Idaho	1,179	79.3	47.8
Illinois	1,148	72.8	41.1
Indiana	1,182	90.9	49.2
Kentucky	803	86.6	62.0
Minnesota	2,386	75.2	36.3
Montana	1,183	***	35.6
New York	1,183	79.1	32.8
North Carolina	1,528	89.9	56.7
North Dakota	628	90.4	37.6
Ohio	1,156	75.7	43.8
Rhode Island	1,277	75.4	38.1
South Carolina	1,216	83.7	58.2
Tennessee	1,207	83.8	66.2
Utah	1,162	92.3	69.3
West Virginia	1,177	89.8	63.5
Wisconsin	965	91.4	25.3

*Percentage of eligible respondents contacted who completed interviews.
**Percentage of respondents who did not report consuming any alcohol in the month before the interview. These percentages are adjusted to compensate for the multistage cluster design of the survey and to be representative of each state's population (based on the age and sex distribution of each state's population in 1985).
***Data necessary for computing response rates not available.

To calculate per capita consumption based on self-reports, we assumed that one beer contained 12 oz of 4.5 percent alcohol; one glass of wine 4 oz of 12.9 percent alcohol; and one liquor drink 1 oz of 41.1 percent alcohol. These alcohol percentages are the same coefficients used by the NIAAA to convert the volume of beer, wine and liquor into the volume of absolute alcohol.[9] We added each respondent's estimate of beer, wine, and liquor consumption and multiplied the sum by 12 to determine the total alcohol consumption for each respondent per year. To calculate the mean alcohol consumption by state, we weighted the value of each respondent's total consumption according to his or her probability of selection as a result of the multistage cluster design of the survey.[12] This weighting compensated for the number of persons 18 years of age and older in each household, the number of telephone numbers reaching each household, and variation in cluster size. We also weighted each respondent's total consumption according to the age and sex distribution of the 1985 adult population for each participating state. This procedure provided population-based estimates of per capita consumption that are representative of each participating state.

Using the survey data, we also determined the state-specific prevalence rates of three drinking behaviors: *heavier drinking* (consuming 60 or more drinks during the prior month), *binge drinking* (consuming five or more drinks on at least one occasion during the prior month), and *drinking and driving* (driving at least once during the prior month after having had *perhaps* too much to drink). As was done with the rates of per capita consumption, the state-specific prevalence rates of these behaviors were adjusted to the age and sex distribution of the 1985 adult population for each state, after weighting the responses to account for the multistage cluster design.

We used linear regression to assess the strength of the association between the state-specific per capita alcohol sales and the measures of self-reported alcohol use; the dependent variables were the measures of self-reported alcohol use and the independent variable was per capita sales.

We used computer software from SAS Institute Inc,[13] and Lotus Development Corporation[14] to perform all calculations.

Results

Among the 21 states, per capita alcohol sales varied twofold, from 1.58 gallons per year in Utah to 3.19 gallons per year in Wisconsin (median = 2.49 gallons) (Table 2). Per capita alcohol consumption varied two and one half-fold, from 0.40 gallons per year in Utah to 1.06 gallons per year in New York (median = 0.72 gallons). Self-reported per capita consumption, when expressed as a percentage of per capita sales, ranged from 21.6 percent in Tennessee to 40.5 percent in New York (median = 28.2 percent) (data not shown).

States that ranked higher in alcohol sales also tended to rank higher in self-reported consumption (Table 2). For example, of the four highest-ranking states in sales (Wisconsin, Arizona, California, and Florida), Wisconsin and Florida both ranked second, Arizona ranked sixth, and California ranked seventh in self-reported consumption. The four states that ranked lowest in sales (Utah, West Virginia, Kentucky, and Tennessee) also ranked lowest in self-reported consumption.

Per capita sales showed a strong linear relation with self-reported consumption among the 21 states (Figure 1). The correlation between sales and consumption was 0.81, with a β coefficient of 0.34 (95 percent confidence interval = 0.23, 0.45) (Table 3). The β coefficient indicates that the average per capita increase for this group of states was 0.34 gallons of self-reported alcohol consumption for each gallon increase in per capita sales of alcohol.

We also assessed the strength of association between sales and self-reported consumption among states in two subgroups: the 13 states for which beverage sales and tax receipt figures were used to determine alcohol sales; and the remaining eight states for which alcohol shipments records were used to determine alcohol sales. The correlation between sales and consumption for states in the first group ($r = 0.70$) was similar to the correlation for states in the second group ($r = 0.74$).

The rates of the three drinking behaviors varied from state to state (Table 2). The prevalence of heavier drinking varied threefold, from 3.8 percent in Utah to 11.5 percent in Illinois (median = 7.1 percent). The prevalence of binge drinking varied almost fivefold, from 5.7 percent in Tennessee to 27.8 percent in Wisconsin (median = 16.6 percent). The prevalence of drinking and driving varied sixfold, from 1.5 percent in Kentucky and Tennessee to 9.4 percent in Wisconsin (median = 3.5 percent).

As was found for self-reported alcohol consumption, the prevalence estimates for each of the three drinking behaviors were correlated with per capita sales (Table 3): heavier drinking $r = 0.74$, binge drinking $r = 0.59$, and drinking and driving $r = 0.51$.

Discussion

Our analysis found that alcohol sales and self-reported drinking behaviors are strongly correlated and provide com-

TABLE 2—Annual per capita Alcohol Sales, Self-Reported Consumption of Alcohol, and Prevalence of Self-Reported Drinking Behaviors, by State, 1985

State	Per Capita Sales (gallons)	Self-Reports

*Numbers in parentheses indicate the rank order (high to low) of the 21 states for each measure of alcohol use. The same ranking number was assigned to states with identical values.

FIGURE 1—Regression Analysis of per capita Sales and per capita Consumption of Alcohol for 21 States, 1985
NOTE: Data points for the 21 states are shown with the fitted regression line, its equation, and the correlation coefficient. Per capita consumption was based on self-reports.

TABLE 3—Summary of Simple Linear Regression Analyses: Annual per capita Alcohol Sales by Four Measures of Alcohol Use from Self-Reports in 21 States, 1985

Measures of Alcohol Use from Self-Reports	β Coefficient*	r	R^2
Per Capita Alcohol Consumption in Gallons	.34 (.23,.45)**	.81	.66
Prevalence of Heavier Drinking	.03 (.02,.05)	.74	.55
Prevalence of Binge Drinking	.07 (.03,.11)	.59	.35
Prevalence of Drinking and Driving	.02 (.01,.04)	.51	.26

*The β coefficient represents the amount of increase in each measure of self-reported alcohol use for each gallon increase in per capita sales of alcohol.
**Numbers in parentheses indicate the 95 percent confidence intervals for the β coefficients.

plementary sources of information. However, each measure has its limitations.

State-specific sales may overestimate consumption in states where alcohol is often purchased by out-of-state visitors. An example is the District of Columbia (DC), which participated in the 1985 Behavioral Risk Factor Surveillance System but was excluded from our analysis because DC is more comparable to a large metropolitan area than to a state. Compared with the results for the 21 states, alcohol sales were disproportionately higher in DC relative to self-reported consumption. This finding is due in part to the purchase of alcohol by tourists and residents from nearby states.

An additional limitation to using alcohol sales to monitor alcohol use is that alcohol that is purchased may not be consumed, either because of wastage (unfinished drinks, spillage) or because of stockpiling at the wholesale, retail, and consumer levels. Although the problem of wastage may be negligible,[4] stockpiling can greatly bias estimates of alcohol use.[15]

In contrast to sales data which provide information only about total alcohol consumption, population surveys can be used to assess both consumption and self-reported drinking behaviors. However, these surveys also have well-recognized problems.[4,6,16] Surveys of self-reported alcohol use uniformly produce lower estimates of total alcohol consumption than do analyses of alcohol sales data.[4,7,8] In previous surveys, self-reported consumption has accounted for only 40–60 percent of alcohol sales, with some reports as low as 26–30 percent of sales.[4] In our study, self-reported consumption accounted for 22–41 percent of alcohol sales. Most telephone surveys are unlikely to include certain segments of the population—such as college students and young men living on military bases—who often are drinkers. Also, population surveys generally undersample heavy drinkers because many of these persons refuse to participate or cannot be located. An additional problem is reporting bias: respondents who are concerned about the social acceptability of their alcohol use may give lower estimates of consumption.

Estimates of self-reported consumption also suffer from the approximations involved in calculating the volume of alcohol consumed per drink. The considerable variation in the size and concentration of alcohol per drink makes estimates of total consumption inexact. This problem has increased with the recent introduction of low-alcohol-content drinks, such as "light" beers and wine "coolers."

Despite all these limitations of sales data and of surveys of self-reported alcohol use, we found a strong correlation between per capita sales and per capita consumption based on self-reports. Per capita sales were also strongly correlated with self-reported heavier drinking, binge drinking, and drinking and driving for the 21 states. These three behaviors do not necessarily identify individual alcohol abusers, nor do they provide accurate measures of problem drinking in a population. However, the prevalence of these behaviors may represent indirect measures of problem drinking by indicating the percentage of a population at increased risk for alcohol-related problems, especially injuries.[17,18]

The results of this study may have been influenced by age considerations. The per capita consumption estimates from sales data were based on each state's number of residents aged 14 and older, as an estimate of the drinking population.[9] Changing the assumed size of the drinking population would affect the calculated rates of per capita consumption from sales data. Furthermore, the surveys included persons only 18 years and older and thus did not reflect consumption and drinking behaviors among younger persons.

Because our study examined ecological associations between alcohol sales and patterns of alcohol use, it was not possible to determine the reasons for the observed correlations between per capita sales and the three drinking behaviors. However, our results are consistent with several theories of alcohol use, including the distribution of consumption model.[19] This theory states that there is a constant relation between per capita alcohol consumption and the prevalence of heavy drinking and suggests that the average alcohol consumption in a population is positively correlated with the prevalence of problem drinking.

We conclude that per capita sales of alcohol generally parallel self-reported consumption and drinking patterns suggestive of high-risk behavior. Although public health officials need to be aware of the limitations of both sales data and self-reports, the high degree of correlation between these two measures of alcohol use suggests that it is reasonable to use alcohol sales for monitoring alcohol consumption when other sources of information are not available.

Physician Supply Projections to be Re-Examined

Projected manpower needs through the year 2010 in six medical specialties will be re-examined and revised as indicated under a contract awarded to Abt Associates Inc., of Cambridge, Massachusetts. The 13-month, $279,463 project, funded by the Health Resources and Services Administration (HRSA), Division of Medicine, will update projections made in 1980 by the Graduate Medical Education National Advisory Committee (GMENAC) for the fields of family practice, general pediatrics, obstetrics-gynecology, general internal medicine, general surgery, and general and child psychiatry.

The project will involve professional organizations representing these six specialties, and will use Bureau of Health Professions physician supply projections through 2010 adjusted to incorporate the supply of osteopathic physicians. The activity will also include a qualitative assessment of the impact that various economic, social, and behavioral constraints, such as problems of the underserved population, would have on the balance between physician supply and national needs.

Cesarean Section Use and Source of Payment: An Analysis of California Hospital Discharge Abstracts

RANDALL S. STAFFORD, PHD, MS

Abstract: This study assessed the relation between payment source and cesarean section use by analyzing California data on hospital deliveries. Of 461,066 deliveries in 1986, cesarean sections were performed in 24.4 percent. Women with private insurance had the highest cesarean section rates (29.1 percent). Successively lower rates were observed for women covered by non-Kaiser health maintenance organizations (26.8 percent), Medi-Cal (22.9 percent), Kaiser (19.7 percent), self-pay (19.3 percent), and Indigent Services (15.6 percent). Vaginal birth after cesarean (VBAC) occurred more than twice as frequently in women covered by Kaiser (19.9 percent) and Indigent Services (24.8 percent), compared to those with private insurance (8.1 percent). Sizable, although less pronounced, associations between payment source and cesarean section use were noted for the indications of breech presentation, dystocia, and fetal distress. Accounting for maternal age and race/ethnicity did not alter these findings. Variations in the use of cesarean section have a substantial financial impact on health care payors. (*Am J Public Health* 1990; 80:313–315.)

Introduction

Medical care decisions are influenced by non-clinical factors, such as health care financing.[1–3] Cesarean section is the most common hospital surgical procedure in the United States,[4] accounting for 24.4 percent of all deliveries in 1987.* The quadrupling of US cesarean section rates in the past 15 years has led to concerns regarding maternal and perinatal outcome, as well as health care costs.[5]

Past studies suggest that women covered by private insurance have the highest cesarean section rates.[6–8] Women covered by Medicaid, those covered by health maintenance organizations (HMOs) and those without a source of payment (self-pay) have lower C-section rates. Lower C-section rates also are observed for teaching hospitals,[9] public hospitals,[6,8] and salaried physicians.[10] Unfortunately, past research has not controlled adequately for the population characteristics (case-mix) of different payors or organizational settings.

This report investigates the relationship between hospital payment source and the use of cesarean section by employing 1986 discharge abstract data from California hospital deliveries.

Methods

Hospital Discharge Data

The Office of Statewide Health Planning and Development collects information on every non-military hospital discharge in California;[11] data for 1986 included 461,066 hospital deliveries.

Cesarean section use was determined via ICD-9-CM procedure codes. Initial categories for expected source of payment for hospitalization were combined into seven distinct payment methods: Private Insurance (Blue Cross/Blue Shield and other private insurance), Kaiser Permanente, Other (non-Kaiser) HMOs, Medi-Cal (the California Medicaid program), Self-Pay, Medically Indigent Services, and Other Payors. Women with HMO coverage delivering in Kaiser Hospitals were assigned to Kaiser Permanente, all other HMO deliveries were assigned to Other HMOs.

Diagnostic information was available as ICD-9-CM codes. A standard and widely employed hierarchy of mutually exclusive diagnoses which accompany cesarean section was adopted for this study.[12,13] From highest to lowest priority, these were: previous cesarean section (ICD-9-CM 654.2), breech presentation (652.2 and 669.6), dystocia (653 and 660-662, except 661.3), fetal distress (656.3), and all other diagnoses (remaining codes in 642-663, and 669, except 669.1-669.5).[12,13] When more than one diagnosis was present for a delivery, the highest priority diagnoses was assigned regardless of its order on the discharge abstract. Maternal age was defined in five-year categories (<20, 20–24, 25–29, 30–34, 35+). Five race/ethnicity categories were employed: White, Black, Hispanic, Asian and Others/Unknown.

Statistical Methods

Cesarean section rates by payment source for individual primary indications were calculated. Confidence intervals were calculated for the cesarean section rates of each payor. Payors whose confidence intervals do not overlap can be considered different at a level of $p < 0.05$, after accounting for multiple comparisons between payors.[14]

To assess the constancy of the relation between payment source and cesarean section rates, the sample was simultaneously stratified by accompanying diagnoses, maternal age, and race/ethnicity. To further validate the findings derived from the above methods, logistic regression analysis was employed to simultaneously estimate the independent effects of payment source, accompanying diagnoses, maternal age, and race/ethnicity. The results of this analysis closely agreed with those from the tabular analysis (details available upon request to author).

Results

In 1986, 112,730 cesarean sections were performed in California hospitals, a cesarean section rate of 24.4 percent. Private Insurance (35 percent) and Medi-Cal (27 percent) were the dominant payors for hospital deliveries (Table 1).

Cesarean section rates varied widely by payment source. Women covered by Private Insurance had the highest cesarean section rates (29.1 percent) (Table 1). Indigent women had the lowest cesarean section rates, with only 15.6 percent being delivered abdominally.

TABLE 1—Cesarean Section Rates by Payment Source, Hospital Deliveries, California, 1986

Payment Source	Total Deliveries	Percentage of all Deliveries	C-Section Rate (95% CI)
Private Insurance*	161,847	35.1	29.1 (28.8, 29.4)
Other HMOs	46,034	10.0	26.8 (26.3, 27.4)
Medi-Cal	122,792	26.6	22.9 (22.6, 23.2)
Kaiser Permanente	51,589	11.1	19.7 (19.2, 20.1)
Self-Pay	49,292	10.7	19.3 (18.8, 19.8)
Indigent Services	10,322	2.2	15.6 (14.6, 16.5)
Other Payors**	19,190	4.2	20.2 (19.5, 21.0)
Total	461,066	100.0	24.4 (24.3, 24.6)

*Includes Blue Cross/Blue Shield and Other Private Insurance.
**Includes Medicare (658 deliveries), Workers' Compensation (104), Title V (208), Other Governmental Payors (13,220), Other Non-governmental Payors (3,709), and No Charge (1,292).

Repeat cesarean sections accounted for 36 percent of all cesareans (Table 2). Large payor differences were observed in women with previous cesarean sections, with an ordering of payors similar to that for all indications (Table 3). Repeat cesarean section rates varied from 91.9 percent for Private Insurance to 75.2 percent for Indigent Services, the rate of vaginal birth after cesarean (VBAC) in indigent women (24.8 percent) was three times that in women with Private Insurance (8.1 percent).

Cesarean section for breech presentation exhibited a distinct pattern by payor. Kaiser had a relatively high breech cesarean rate (88.3 percent); indigent women the lowest (78.5 percent) (Table 4).

Cesareans for dystocia accounted for 32 percent of all cesareans. For this accompanying diagnosis, relatively high cesarean rates were experienced by Private Insurance (65.9 percent, 65.1–66.7), Other HMOs (65.3 percent, 63.7–67.0), Medi-Cal (64.6 percent, 63.5–65.7), and Self-Pay (61.4 percent, 59.7–63.1). Women covered by Indigent Services (56.9 percent, 52.3–61.5) and Kaiser (58.8 percent, 55.4–62.3) had significantly lower rates.

Deliveries with the diagnosis of fetal distress showed a pattern similar to that for all deliveries. Other HMOs (33.0 percent, 30.9–35.0) and Private Insurance (31.5 percent, 30.4–32.6) had the highest rates, while indigent women had the lowest (21.6 percent, 18.4–24.9).

TABLE 2—Cesarean Section Rates by Primary Accompanying Diagnosis, Hospital Deliveries, California, 1986

Primary Accompanying Diagnosis	Deliveries	Percentage of all Deliveries	Cesarean Sections	Percentage of all Cesareans	Cesarean Section Rate
Previous Cesarean	45,188	9.8	40,274	35.7	89.1
Breech	13,926	3.0	12,112	10.7	87.0
Dystocia	55,895	12.1	35,896	31.9	64.2
Fetal Distress	39,058	8.5	11,134	9.9	28.5
Other Diagnoses*	111,156	24.1	12,926	11.5	11.6
None**	195,843	42.5	388	0.3	0.2
Total	461,066	100.0	112,730	100.0	24.4

*Includes the following diagnoses occurring without previous cesarean section, breech presentation, fetal distress, or dystocia: antepartum hemorrhage, hypertension, excessive vomiting, pre-term labor, prolonged pregnancy, other pregnancy complications, maternal infections, other medical conditions in pregnancy, multiple gestation, other malpresentation, anatomical abnormalities of pelvis, fetal abnormalities, placental problems, polyhydramnios, other amniotic complications, other indications for care, umbilical cord complications, and other complications of labor and delivery.
**Includes deliveries lacking any diagnosis classifiable to any of the above categories.

TABLE 3—Cesarean Section Rates for Women with Previous C-Sections, by Payment Source, Hospital Deliveries, California, 1986

Payment Source	Total Deliveries	Percentage of Payor's Deliveries	C-Section Rate (95% CI)
Private Insurance	18,837	11.6	91.9 (91.4, 92.4)
Other HMOs	5,064	11.0	91.7 (90.6, 92.7)
Medi-Cal	11,444	9.3	90.6 (89.9, 91.4)
Kaiser Permanente	4,385	8.5	80.1 (78.5, 81.7)
Self-Pay	3,353	6.8	81.9 (80.1, 83.7)
Indigent Services	660	6.4	75.2 (70.7, 79.6)
Other Payors	1,445	7.5	82.9 (80.3, 89.5)
Total	45,188	9.8	89.1 (88.7, 89.5)

TABLE 4—Cesarean Section Rates for Breech Presentation, by Payment Source, Hospital Deliveries, California, 1986

Payment Source	Total Deliveries	Percentage of Payor's Deliveries	C-Section Rate (95% CI)
Private Insurance	5,510	3.4	89.7 (88.6, 90.8)
Other HMOs	1,381	3.0	89.9 (87.7, 92.1)
Medi-Cal	3,400	2.7	83.9 (82.2, 85.6)
Kaiser Permanente	1,424	2.8	88.3 (86.0, 90.6)
Self-Pay	1,416	2.9	81.6 (78.8, 84.4)
Indigent Services	247	2.4	78.5 (71.4, 85.6)
Other Payors	548	2.9	85.0 (80.9, 89.1)
Total	13,926	3.0	87.0 (86.2, 87.8)

For deliveries with other accompanying diagnoses, women with Private Insurance had cesarean section rates (14.4 percent, 13.9–14.9) nearly double those of indigent women (7.7 percent, 6.3–9.1).

Of the 125 subpopulations formed from all combinations of age-group (five categories), race/ethnicity (five categories), and accompanying diagnoses (five categories), 105 had three or more payors with more than 20 deliveries. Among these subpopulations, Private Insurance had the highest cesarean rates in 42 percent and non-Kaiser HMOs in 30 percent. Medi-Cal (8 percent), Other Payors (8 percent), Self-Pay (6 percent), Kaiser (6 percent), and Indigent Services (1 percent) had the highest cesarean rates less frequently (detailed tables available on request to author).

Discussion

This study indicates that cesarean section use is strongly associated with the source of payment for obstetrical care, after stratifying for available patient characteristics. Differences between payors were particularly large for women with previous cesarean sections, currently a controversial area of obstetrical practice.[15,16]

Because payment source is not randomly assigned to women, stratification by patient characteristics is an important aspect of this study. Two potential limitations in this process must be noted. First, hospital discharge abstracts have a limited number of data elements available, and do not include information on parity, gravidity, and birthweight. Second, potential problems in data accuracy and completeness may diminish the discharge data's ability to reflect

clinical differences between patients. In particular, dystocia and fetal distress may be subject to biased recording and are more likely to be recorded if a cesarean section is performed.

Direct or indirect financial incentives, as well as additional factors such as access to technology,[8] physician work schedules,[17] hospital teaching status,[8] hospital ownership status,[6,9] patient socioeconomic status,[18] and medical malpractice concerns may contribute to the observed payor differences. In addition, it is possible that the underlying delivery preferences of women or their physicians may vary systematically by source of hospital payment.

The high cesarean rate for Private Insurance is consistent with the financial incentives of fee-for-service practice that favor higher cesarean section rates. The existence of incentives does not necessarily imply that physicians consciously seek greater income. Such incentives may function via implicit clinical standards.

The moderate Medi-Cal cesarean rates are consistent with incentives to perform cesarean section that may be tempered by the reduced physician and hospital reimbursements provided by Medi-Cal.[19] Women with Medi-Cal also tend to deliver in hospitals where there may be other constraints on cesarean section use.

While HMOs have been shown to have lower cesarean section rates than private insurance,[7,20] the current findings suggest this is the case only in large, hospital-based HMOs. The data indicate that the cesarean section experience of HMOs other than Kaiser closely resembles that of private insurance. Besides Kaiser's incentive to avoid excessive cesarean section use, the prominence of peer review and fixed work schedules also may contribute to the lower Kaiser cesarean rates.

The desire of Self-Pay women to avoid the higher cost of cesarean section may discourage cesarean section use. In addition, Self-Pay women make disproportionate use of public hospitals, where additional institutional constraints may reduce cesarean use.

The low rates of cesarean section in women covered by Indigent Services is consistent with the economic constraints of the county hospitals where these women deliver. At the same time, many of these hospitals have teaching programs which, like Kaiser, are more likely to have fixed work schedules and emphasize peer review.

The potential costs savings to payors of fewer cesarean sections may be gauged using 1986 estimates of physician and hospital costs, and Kaiser's moderate cesarean section rate of 19.7 percent. Insurance claims data for the western US indicate that in 1986 cesarean sections were 84 percent more costly than vaginal deliveries ($5,000 versus $2,720).[21] Based on these figures, if the cesarean section patterns of Kaiser were adopted, private insurance plans, non-Kaiser HMOs and Medi-Cal potentially would save $51 million annually by avoiding 22,500 cesarean sections. This may be an underestimate of cost savings, however, because Kaiser's rate is nearly twice that suggested as an optimal cesarean section rate.[22,23]

The Effects of Case Definition in Maternal Screening and Reporting Criteria on Rates of Congenital Syphilis

DEBORAH A. COHEN, MD, MPH, DAVID BOYD, MPH, IRENE PRABHUDAS, MPH, AND LAURENE MASCOLA, MD, MPH

Abstract: Reports of congenital syphilis in 1987 were reviewed to determine how new national guidelines for defining congenital syphilis would influence reported rates in Los Angeles County. After reviewing all reported reactive serologic tests for syphilis, we found 166 additional cases, resulting in a 426 percent increase in the 1987 reported rate of congenital syphilis. Rates of congenital syphilis are dependent upon surveillance practices, screening policies, and case definition. (*Am J Public Health* 1990; 80:316–317.)

Introduction

Until January 1988, the Centers for Disease Control (CDC) had asked health departments to report cases of congenital syphilis based upon Kaufman's criteria.[1] This complicated system classified infants as "definite," "probable," "possible," and "unlikely" based upon symptoms and laboratory findings at birth and serological tests collected over time. A major shortcoming is the variability with which follow-up data might be available, making the accurate reporting of cases difficult. A second problem was that Kaufman's criteria excluded stillborn infants of mothers with untreated syphilis.[2]

In January 1988, the CDC issued new guidelines for classifying and reporting cases of congenital syphilis.[3] The new guidelines broadened the case definition to include all liveborn and stillborn infants with reactive serologic tests for syphilis (STS) delivered by women with a history of untreated syphilis. Such infants are now considered to be "compatible" with a diagnosis of congenital syphilis, regardless of symptoms. This category essentially combined and simplified the "probable" and "possible" classifications of Kaufman's criteria, as well as broadening it to include fetal deaths.

In order to determine how adoption of the new CDC criteria would affect the reported rates of congenital syphilis, the Los Angeles County (California) Sexually Transmitted Disease Program reviewed its 1987 congenital syphilis caseload.

Methods

In Los Angeles County, all cases of syphilis and all laboratory findings consistent with syphilis must be reported to the Sexually Transmitted Disease (STD) Program of the Department of Health Services.[4] Because California reporting requirements only include symptomatic cases of "probable" and "possible" congenital syphilis, asymptomatic seropositive infants with no other laboratory findings have not been routinely counted in Los Angeles morbidity reports. Instead, these infants have been classified as "epidemiologically treated" or non-cases, because they received treatment for syphilis without supportive evidence that they were truly infected. All reports of "epidemiologically treated" infants were reviewed to distinguish those infants whose mothers had a documented history of adequate treatment prior to delivery ("unlikely" cases) from those infants whose mothers were not treated for syphilis prior to delivery ("compatible" cases). Unreported infants with negative STS born to untreated syphilitic mothers were not included in the review.

To determine the number of fetal deaths in 1987 that occurred among the women with untreated syphilis, we matched all fetal death records (n = 1133) with all STD records by last name and address. As matching in this way might not identify all such outcomes, we reviewed fetal death and syphilis serology records from three public and two private hospitals reporting the largest numbers of congenital syphilis cases in 1987.

Results

Using California's congenital syphilis reporting criteria, Los Angeles County reported 39 cases of congenital syphilis in 1987. An additional 189 infants received presumptive treatment in 1987. Of these, 115 could be classified as "compatible" with a diagnosis of congenital syphilis under the new CDC criteria. In addition, the review of fetal death

**calculated using Fischer's Exact Chi-Square

records identified 42 among women with untreated syphilis, four among women with no documentation of treatment for syphilis, and five among women who had been treated within the week preceding the stillbirth. The total of 205 cases represent nearly a five-fold increase in the risk of congenital syphilis in Los Angeles County.

When stratified by race, the 39 officially reported cases in 1987 included only one White and no Asian-Americans (Table 1). When all 205 cases were included all race groups were represented. The new rates of congenital syphilis were highest among Blacks, 7.0 times and 20.2 times higher than Hispanics and Whites, respectively.

When cases were divided by ethnicity and source of report, infants born at public hospitals were more likely to be diagnosed as being "compatible" with congenital syphilis than infants born at private hospitals for all race groups (Table 2).

Discussion

Using the expanded case definition, cases of congenital syphilis increased nearly five-fold in 1987, and even this increase is probably an underestimate. Laboratory reporting of reactive STS results is often variable and, particularly in the private sector, pregnancy status may not be reported with a reactive serology. STS is not mandatory at delivery in California; 48 percent (19/39) of the symptomatic reported cases in 1987, diagnosed only when they developed the florid symptoms of congenital syphilis, were missed at delivery. It is probable that many more at-risk infants were not identified due to lack of screening.

The high rate of congenital syphilis among Blacks is consistent with the rates of reported infectious syphilis in Los Angeles (Blacks 300.6/100,000, Whites 10.3/100,000, Hispanics 42.5/100,000).[5] In our series Black infants were more likely to be among those who were not diagnosed until symptoms developed many weeks after delivery (18/19). They were less likely to have prenatal care and more likely than Hispanics to deliver in private sector hospitals where delivery screening is not routine.

Public hospitals in Los Angeles County routinely perform the STS in the first and third trimesters of pregnancy and at delivery. While women who receive care there may be at greater risk for syphilis, they are more likely to be diagnosed with syphilis than in private hospitals where screening is at physician discretion. Since the distribution of livebirths and stillbirths in public hospitals differs from the distribution countywide, overrepresenting Hispanics and underrepresenting all other race groups, these racial-ethnic comparisons may be inaccurate.

The 205 cases of congenital syphilis defined by the new CDC criteria are a better reflection of the extent of the local congenital syphilis problem than the 39 defined by a modified Kaufman's criteria because more infants at risk are included—not just those few who develop classic symptoms of congenital syphilis. While the new CDC criteria overestimate the cases by including uninfected infants who may have a reactive STS due to passive transfer of maternal antibody, many syphilis-related stillbirths are uncounted because the mother is not screened at delivery and the association is never made. Because there is no way to differentiate whether an asymptomatic infant born to a mother with untreated syphilis is healthy or infected, all at-risk infants are treated and should be counted, regardless of whether they have reactive STS. In Los Angeles County, because four infants born with non-reactive STS in 1988 were not appropriately treated at delivery (their mothers' sera were reactive), they subsequently developed florid symptoms of congenital syphilis.

These data demonstrate that reported cases of syphilis are greatly affected by both definition, reporting criteria, and maternal delivery screening practices. For rates to be comparable between reporting jurisdictions, a clear case definition and universal delivery screening for mothers of both stillbirths and livebirths are necessary.

End State Renal Disease among Native Americans, 1983–86

JEFFREY M. NEWMAN, MD, MPH, ANTHONY A. MARFIN, MD, PAUL W. EGGERS, PHD, AND STEVEN D. HELGERSON, MD, MPH

Abstract: We used data reported to Medicare from 1983 through 1986 to determine the incidence of end-stage renal disease (ESRD) among Native Americans and Whites in the United States. The 1,075 Native American cases represented an annual incidence, age-adjusted to the White population, of 269 per million, 2.8 times the rate for Whites. Fifty-six percent of Native American cases and 27 percent of the White cases were attributed to diabetes, indicating that ESRD is a major problem. Diabetes control provides the greatest opportunity for prevention. (*Am J Public Health* 1990; 80:318–319.)

Introduction

Chronic diseases, including end-stage renal disease (ESRD) and diabetes, are major public health problems for Native Americans; in the period 1981–83, their age-adjusted mortality rate due to renal disease was 11.7 per 100,000, while the 1982 rate for all US races was 4.5 (National Center for Health Statistics data provided by Thomas Welty, MD, MPH). Although the incidence of ESRD among all racial groups appears to have risen dramatically since the mid-1970s, when federal funding for ESRD treatment was initiated, the increase has been more rapid among the minority populations than among the White population.[1,2]

To compare the distribution of ESRD treatment onset among Native Americans and Whites, we examined the Health Care Financing Administration's ESRD Medical Information System. This system, designed for fiscal management, includes data on over 90 percent of ESRD treatment in the United States.[1]

Methods

The HCFA Medical Evidence Report form is completed for every patient receiving dialysis or renal transplantation reimbursed by HCFA by the medical care provider. Race categories are "Native American" (American Indian or Alaskan Native), Asian or Pacific Islander, Black, White, and unknown. (Ethnicity has not been uniformly recorded.) We reviewed data for all ESRD referrals who were identified as "Native American/American Indian" and as "White" for the period 1983–86: age, sex, year of treatment initiation, state of residence at the time of initiation, and primary diagnosis.

To determine the extent of one form of race misclassification, the case reports designated as American Indian for the period 1982–86 were examined for any names that suggested apparent origin from India or other Asian or Pacific Island countries.

The estimated number of diabetic Native Americans in 1987 was 72,000 in a total population of 1.6 million (diabetes prevalence from Indian Health Service ambulatory care data, provided by Sarah Valway, DMD, MPH); and the national figure for diabetic Whites in 1985 was 4,892,000 out of a total population of 197,576,000.[3] We used these national estimates to calculate the incidence of ESRD among Native Americans and Whites and to determine the association between ESRD and diabetes. Population data from the 1980 US Census were used to calculate overall, age-specific, and sex-specific rates in Native Americans and Whites. We used the direct method to age-adjust Native American ESRD rates to the 1980 White population.

Results

Of cases of ESRD treatment initiation reported to Medicare from 1983 to 1986, 1,075 were categorized as American Indian and 75,291 as White. Fifty-eight percent of the Native American cases resided in the five states with the largest Native American population, in which the crude incidence was 219 per million, compared to 140 per million in 42 other states reporting 1 to 50 American Indian cases.

The age-adjusted incidence of ESRD for Native Americans was 269 per million, 2.8 times that for Whites (Table 1). The age-specific rate ratios for Native Americans were highest in the 45–64 age group.

The proportion of ESRD attributed to diabetes was greater for Native Americans than for Whites (55.5 percent vs. 26.9 percent, $p < 0.01$) (Figure 1). In the Native American total population, the age-adjusted incidence of ESRD attributed to diabetes was 149 per million, 5.8 times the rate for Whites.

In the estimated Native American diabetic population, the incidence of ESRD attributed to diabetes was 2,073 per million, 2.0 times the rate for Whites. The incidence of ESRD associated with other causes in the non-diabetic population was 78 per million for American Indians, 1.1 times the rate for

Whites. The relative risk for ESRD associated with diabetes is 27 for Native Americans, compared with 14 for Whites.

Review of the ESRD cases from 1982–86 classified as American Indian revealed that the names in 7.4 percent of the cases (93/1265) were highly suggestive of origin from India or other Asian or Pacific Island countries. This apparent race misclassification was less prevalent in cases attributed to diabetes (3.8 percent or 26/678) than in those attributed to other causes (11.4 percent or 67/587), and in the reports submitted from the five states with more than 50 Native American ESRD cases (4.7 percent or 35/739) than from the other states (11.0 percent or 58/526). There was no association between apparent race misclassification and the sex of the referred patient, the age of the referred patient, the year of referral, the incidence rate of ESRD, or the size of the Native American population within the state of referral.

Discussion

For Native Americans, the age-adjusted incidence of ESRD treatment reported to Medicare from 1983 through 1986 was 2.8 times that for Whites. The majority of Native American ESRD cases were attributed to diabetes; the diabetes-attributed incidence was 5.8 times that for Whites. These data are consistent with other measures of the burden of diabetes for Native Americans.[4] While the prevalence of diabetes is higher in Native Americans, the higher incidence of diabetes-attributed ESRD in its diabetic population than among Whites with diabetes suggests that severity of diabetes and other factors among Native Americans are also involved. However, this finding may also be due to an underestimate of the prevalence of diabetes in Native Americans.

Our review of names of cases designated as American Indian indicates that the observed incidence of ESRD is not substantially inflated by one type of race misclassification, that of apparent Asians as American Indian. Because of mixed heritage, there may also be some misclassification between Whites and American Indians. It is likely that misclassification of American Indians as White exceeds misclassification of Whites as American Indian, suggesting that the observed American Indian incidence may be an underestimate. Further study of race misclassification may add to the utility of the ESRD data set for surveillance by the Indian Health Service.

Although the type of diabetes was not designated, Native Americans have a high prevalence of non-insulin dependent diabetes mellitus and a low prevalence of insulin-dependent diabetes, which is consistent with their older age of onset of ESRD. A recent study of the Pima Indians demonstrated a high incidence of ESRD attributed to non-insulin dependent diabetes, and a strong association with its duration.[5]

These findings indicate the need for prevention of ESRD in Native Americans. Potential interventions include the primary prevention of non-insulin dependent diabetes[6] and early identification of renal disease in persons with diabetes, to intensify diet and blood pressure control.[7]

Mortality from Infectious Diseases among New Mexico's American Indians, Hispanic Whites, and Other Whites, 1958–87

THOMAS M. BECKER, MD, CHARLES WIGGINS, MSPH, CORINNE PEEK, BA, CHARLES R. KEY, MD, AND JONATHAN M. SAMET, MD

Abstract: To examine ethnic differences in infectious disease-related mortality in New Mexico's American Indian, Hispanic White and other White populations, we analyzed vital records data from 1958 to 1987. We found that for most infectious causes, American Indians had the highest mortality rates, followed by Hispanics. The state's minority populations remain at increased risk for infectious disease mortality. (*Am J Public Health* 1990; 80:320–323.)

Introduction

Trends in infectious disease mortality among minority groups in the United States have not been adequately examined. New Mexico has three major ethnic populations: American Indians, Hispanic Whites and other Whites. The cultural and genetic backgrounds of these populations are distinct, and the three ethnic groups have differing levels of education and income, with over 40 percent of American Indians and 23 percent of Hispanics living below the poverty level.[1] Many American Indians in New Mexico live traditional life-styles, often in crowded homes with no running water.[2] Despite gradual economic improvement in the state, many disadvantaged minority persons still live in conditions similar to those in developing countries,[3–5] with the attendant risks of acquiring many types of infectious diseases. To examine ethnic differences in infectious disease-related mortality in New Mexico, we analyzed vital records data collected from 1958 to 1987 for American Indians, Hispanic Whites, and other Whites in the state.

Methods

We obtained coded death certificate data for New Mexico residents for the years 1958–87 from the New Mexico Bureau of Vital Statistics. Cause of death on the certificates was coded according to seventh, eighth, and ninth revisions of the International Classification of Diseases (ICD) for the years 1958–68, 1969–78, and 1978–87.[6–8] Conforming to ICD categories, we examined data for: tuberculosis, other (non-tuberculous) infections and parasitic diseases, influenza, pneumonia, kidney infections, and meningitis. Due to ICD classification coding changes, we did not examine diarrheal disease.

The Bureau of Vital Statistics assigned ethnicity according to information on the death certificates. Hispanic ethnicity was determined by surname of the decedent and the decedent's parents, and specific statements on the death certificates; other White ethnicity by coding as "White" on the certificate, and neither a Spanish surname nor other information to indicate otherwise; and American Indian ethnicity by information on the death certificate. American Indian cases were primarily of the Navajo, Pueblo, Zuni, and Apache tribes. Small numbers of cases prevented inclusion of other racial/ethnic groups in the study. The Bureau of Vital Statistics' assignment of Hispanic and other White ethnicity correlated highly with self-reported ethnic status.[9,10] Among Hispanic cases, no attempt was made to distinguish between recent immigrants to the state and the descendants of early settlers to New Mexico.

Denominators for rate calculations were derived from the censuses of 1960,[11–13] 1970,[14,15] and 1980.[1] Since different techniques were used in each census by the US Census Bureau to identify ethnicity, we adjusted estimates of the Hispanic population from 1960 to 1980 to account for the different enumeration procedures.[9,10] Because of coding changes among the ICD revisions, we standardized case counts to conform to the coding scheme of the eighth revision with the National Center for Health Statistics' comparability ratios.[16,17]

Age-specific and age-adjusted mortality rates were calculated by infectious disease category for the five-year periods, 1958–62, 1963–67, 1968–72, 1973–77, 1978–82, and 1983–87. Age-adjusted rates were standardized to the 1970 US standard million population. We used the Statistical Analysis System[18] for our analyses.

Results

The data show substantial differences in infectious disease mortality among New Mexico's three major ethnic populations during the 30-year study period (Tables 1, 2). Age-adjusted mortality rates for most categories of infectious diseases were generally highest among American Indians, followed by Hispanics, for each time period of the study. The greatest rate differences were evident in most periods for tuberculosis, pneumonia, meningitis, other infections, and parasites, with American Indian rates far exceeding rates for Hispanics and other Whites (Tables 1, 2). Ethnic differences for influenza and kidney infections were less striking (Tables 1, 2).

Dramatic declines in mortality rates were observed for American Indians for tuberculosis and for other infections and parasites (Tables 1, 2). However, mortality for tuberculosis, pneumonia, other infections and parasites tended to be higher for American Indians in the latter years of the study

than for other Whites in the period 1958–1962, 30 years earlier.

Because of elevated mortality rates for infectious causes among young children in New Mexico, we examined age-specific mortality for pneumonia, meningitis, other infections, and parasites by sex and ethnic group among children ages 0–4 years. These data show trends similar to the age-adjusted data for Hispanics, American Indians, and other Whites in the state, with the highest mortality rates for the American Indian children (Table 3).

Discussion

Our data show that New Mexico's three major ethnic populations followed the national trend[19] of decreasing infectious disease-related mortality, but also indicate substantial ethnic differences in these mortality rates. These differences in mortality rates may be influenced by the disparate cultural beliefs and medical practices in these ethnic groups. Many Navajo, Pueblo, Zuni, and Apache people prefer traditional medicine men to modern medical treatment,[3,4] and some Hispanics use traditional curanderos.[20,21] Any consequent delay in seeking modern medical attention may increase mortality rates. Lack of health care availability can also affect mortality rates. In New Mexico, approximately one-third of Hispanics are medically uninsured, and many of the predominantly Hispanic rural counties are medically underserved.[22] Although the Indian Health Service provides care at no cost to the American Indians, long distances and unimproved roads also lessen health care availability, and have been demonstrated to be a risk factor for Navajo children presenting with infectious diseases.[23]

Our analyses of vital data have certain limitations; these potential sources of bias have been discussed in detail in prior publications.[9,10] In addition, these analyses cannot determine whether the incidence of infections is higher in the minority than in the White majority populations, or whether the incidence of infections is comparable, but the case-fatality ratios are higher in minority populations. Few published studies have directly addressed these issues from a population-based perspective on infectious disease incidence and mortality in the United States. The data from this study emphasize the importance of targeting the state's high-risk minority populations in provision of timely and appropriate medical care to reduce the high rates of mortality from infectious causes in New Mexico.

Feasibility of a Telephone Survey to Study a Minority Community: Hispanics in San Francisco

GERARDO MARIN, PHD, BARBARA VANOSS, PHD, AND ELISEO J. PEREZ-STABLE, MD

Abstract: In two random digit dialing surveys conducted among Hispanics using a modified Mitofsky-Waksberg procedure, we found low refusal rates (4.7% and 3.1%), low assumed noncontact rate (14.0% and 18.3%), and high response rates (88.6% and 88.4%) with limited investment in time (1.58 hours and 1.66 hours per completed interview). These results suggest that Hispanics are willing to participate in telephone surveys and that this method may be feasible and useful for research and evaluation purposes. (*Am J Public Health* 1990; 80:323–326.)

Introduction

Surveys conducted over the telephone can be expected to be particularly useful to study minorities since they provide researchers with an efficient method to collect data with acceptable response rates and low interviewer bias.[1–4] Telephone surveys also allow the use of moderately long interview schedules regardless of respondents' reading and writing abilities. In addition, telephone surveys generally cost less than personal interviews. On the other hand, several investigators have suggested there are problems in identifying and sampling Hispanics; obtaining respondent cooperation; designing valid interview schedules; and controlling biases that may be introduced due to the ethnicity of the interviewer and the language used in the interview.[5–7]

The absence of a telephone at home among a significant proportion of potential respondents can be expected to decrease the representativeness of a sample and limit the generalizability of the results of a survey. Most individuals in the United States have a telephone in their household.[4] In San Francisco, for example, the 1980 Census found that 92 percent of self-identified Hispanic households in those census tracts with 400 or more Hispanics had at least one telephone compared with 94 percent for non-Hispanics. In other major cities telephone ownership among Hispanics averages 85 percent.[8]

We used the random digit dialing procedure for telephone surveys suggested by Mitofsky and Waksberg[9] which eliminates the use of nonworking banks (prefixes) and avoids the use of directories (eliminating the problem of excluding

unlisted numbers) while guaranteeing equal probability of selection for all residential telephone numbers.[1] A recent study with Blacks[10] found this approach particularly efficient in obtaining samples from highly clustered subgroups as is the case of many ethnic/racial minorities living in urban areas of the United States. This paper describes two surveys in which the Mitofsky-Waksberg approach was used to sample Hispanics.

Methods

The surveys were designed to obtain estimates of the prevalence of cigarette smoking[11] and to serve as baselines for the evaluation of a community intervention designed to lower cigarette smoking prevalence among Hispanics in San Francisco. Each interview lasted approximately 15 minutes and included approximately 60 questions dealing with smoking behavior, standard socio-demographic variables, and an acculturation scale.[12] The interviews were conducted in the language of choice of the respondents; 67 percent and 69 percent preferred to use Spanish in the first and second studies, respectively. Interviewers were bilingual (English and Spanish) men and women who received at least 12 hours of training, including role playing and supervised interviewing, before they participated in the study. Training of interviewers was based on procedures for telephone interviewing developed by the Minnesota Heart Health Program and on materials from the Survey Research Center of the University of Michigan.[13]

A household was judged to be eligible when the respondent identified himself/herself as Hispanic, or identified the majority of the residents in the household as "Hispanics." Hispanic ethnicity was ascertained by the respondents' answer to the question "Do you or most of the people in your household consider yourselves to be Hispanics, Blacks, Asians, or Caucasians?" The response to this question was later checked with the respondents' and their parents' reported place of birth and with the respondents' identification with one of the Hispanic subgroups.

Prefix Selection

We selected prefixes that covered census tracts with the largest concentration of Hispanics, according to 1980 census data. This identified 27 tracts with 10 percent or more Hispanic residents. These tracts represented 66.6 percent (N = 55,541) of all Hispanics (N = 83,373) in the city of San Francisco.

In each census tract with high concentrations of Hispanics, three city streets were randomly selected to locate telephone prefixes assigned to residences. This process produced 49 three-digit prefixes out of the 121 prefixes in use in San Francisco. These procedures were conducted separately for each study and in both cases the same 49 three-digit prefixes were identified and used.

Stage One Sampling

A random list of 2,000 different four-digit numbers was generated by a computer and the numbers were randomly assigned to the 49 prefixes. These seven-digit telephone numbers were then assigned to interviewers. When a Hispanic household was reached, the first five digits of that telephone number became a Primary Sampling Unit (PSU). During Study I, a total of 4,326 working numbers were called as part of this first stage in the sampling procedure yielding 259 PSUs. Study II produced 355 PSUs out of the 4,680 working numbers called. Tables 1 and 2 present a summary of the outcome of the calls made in this stage during both studies.

TABLE 1—Summary of Telephone Calls for Study I

Assumed noncontact rate	(15.9)	(18.8)	(18.3)

Stage Two Sampling

A computer-generated list of 99 random two-digit numbers was used to produce the suffixes for each of the PSUs. Each interviewer continued using a given PSU until eight Hispanic households were reached including completed interviews or refusals, or until the list was exhausted including four follow-up calls made within a four-week period to every unanswered number. Tables 1 and 2 present a summary of the outcome of the numbers called in this stage during both studies. A total of 92 PSUs (36 percent) were exhausted before reaching eight Hispanic households during the first study. The corresponding figure for the second study was 95 (25 percent).

Interviewee Eligibility

Within a Hispanic household, the respondent was selected by asking for the resident who had most recently celebrated a birthday and who was between 18 and 65 years of age. Approximately 8 percent of otherwise eligible households failed to meet this criterion (Tables 1 and 2).

A total of 1,669 respondents were interviewed during Study I (Fall 1986). Of these, 44 percent were males and the majority of the respondents (69 percent) were foreign-born with 60 percent of them reporting being born in Central America, 29 percent in Mexico, and the remainder in South America, Cuba, or Puerto Rico. The respondents' mean age was 35.5 years and they reported a mean number of years of

education of 11.6. In Study II (Summer 1987), 2,059 Hispanics were interviewed (42 percent men). The respondents' mean age was 35.5 years while the mean number of years of education was 11.6. The majority (70 percent) were born outside the United States, 60 percent of them in Central America, 28 percent in Mexico, and the remainder in either Cuba, Puerto Rico, or South America.

Results

Response/Refusal Rates

Tables 1 and 2 show the response and refusal rates for both studies. We have adapted Kviz's[14] definition of response rate which is the proportion of completed interviews in terms of the number of eligible respondents (defined here as Hispanics between 18 and 65 years of age). This calculation assumes that those not contacted after four follow-up calls ("lost to survey") were eligibles.[15] This proportion was assumed to be the same as the proportion of eligibles found among telephone numbers that were fully screened. The Stage I response rate, assumed that the proportion of eligibles found among the screened calls 306/3425 (8.9 percent) would be similar to that among the 901 numbers that were "lost to survey." Adding the 80 assumed eligible numbers yielded a response rate of 286/386 (74.1 percent). Response rates for the other stages of both studies were calculated in the same manner noted here and show an overall response rate of 88.6 percent for Study I and 88.4 percent for Study II.

The refusal rates were defined[1] as the proportion of eligible respondents (Hispanics between 18 and 65 years of age) who were contacted but declined to be interviewed. Refusal rates were only 4.7 percent for Study I and 3.1 percent for Study II.

The Assumed Noncontact Rate[1] is an index of the accessibility of respondents or the probability of researchers locating respondents. This index is made up of the proportion of respondents not contacted after four follow-up calls ("lost to survey" in both tables) in relation to the total number of possible eligible respondents. Given that a significant proportion of telephone numbers in San Francisco are unlisted (38 percent according to Pacific Bell), it is not appropriate to estimate the true number of eligible households from an alphabetic telephone directory. Thus, in computing the assumed noncontact rate we are assuming that 25 percent of those respondents "lost to survey" were eligible Hispanics. This assumption reflects twice the number of Hispanics reported to be living in San Francisco in 1985 and therefore produces a very conservative computation of nonresponse rates. In Study I for example, 25 percent of the 1,139 "lost to survey" (N = 285) represent 14 percent of the total number of assumed Hispanic numbers: completed interviews (N = 1,669) plus refusals (N = 83) plus lost to survey (N = 285). The comparable noncontact rate for Study II is 18.3 percent. Figures taken from Wiseman and McDonald's[16] review of the literature show a median noncontact rate of 39.1 percent.

Cost of Survey

Based upon the time spent by all interviewers, we estimated costs of obtaining a completed interview. On the average, interviewers needed to spend 1.58 hours in order to obtain a completed interview during Study I and 1.66 hours during Study II. Each of the completed interviews cost approximately $15 based on paid interviewer and supervisor salaries but excluding overhead, training time, telephone lines, investigators' time, and data management. Interviewers were paid $7.90 per hour in this study.

Discussion

These results suggest that it is feasible and efficient to use random digit dialing techniques to obtain a sample of Hispanics. The similarity in the outcomes of the two studies imply that the findings are fairly stable across time.

The high completion rates and the correspondingly low refusal rates obtained in these surveys compare favorably with those found in studies of other Whites, which range between 66 percent in a study in Chicago[4] to 73.5 percent in a regional survey.[17] The low refusal rates (4.7 percent in Study I and 3.1 percent in Study II) are lower than those of other studies. Wiseman and McDonald[16] in their review of 182 studies using telephone surveys found a median refusal rate of 28 percent while Frey[1] reports refusal rates ranging between 20–25 percent. Low refusal rates among Hispanics have also been reported in a study conducted in Texas[18] where a telephone survey of a sample drawn from Spanish-surnamed individuals produced a refusal rate of 8.8 percent.

The high rate of participation in these surveys by Hispanics was not due to advance publicity about the study. Respondents were informed of the purpose of the study only at the time of the interview. One possible explanation for these results is the presence of a cultural characteristic that promotes cooperation and that dictates positive interpersonal relations—the social script of "simpatia."[19] This cultural norm would move Hispanic respondents to agree to be interviewed in order to maintain a fluid and positive social relationship with the interviewer when the relationship is perceived as nonthreatening and as sanctioned by a respected local institution (the study was introduced as being conducted by a state university in San Francisco).

The generalizability of our results may be limited by the following specific concerns:

- The sampling frame used excluded approximately one-third of the San Francisco Hispanic population according to the 1980 census. Hispanics who are living in census tracts excluded in this study (less than 10 percent Hispanic) may behave differently when asked for an interview over the telephone.
- At least 8 percent of San Francisco Hispanic households may not have a telephone at home and these persons are also excluded from the sample.
- The approach utilized in choosing the prefixes may not produce all of the relevant ones although a third study survey recently concluded by the authors has again identified the same 49 prefixes as the first two studies.
- Finally, San Francisco Hispanics (Central American and Mexican in this survey) may differ from Hispanics residing elsewhere.

Future studies should compare samples gathered with this method with census data in order to address the representativeness of a sample of minority-group respondents obtained through a random digit dialing technique such as the Mitofsky-Waksberg approach. Unfortunately, this analysis cannot be done at the present time due to the high undercount of Hispanics in the 1980 census and the later significant migrations from Cuba and Central America.

Sex-specific and Race-specific Hip Fracture Rates

SHIRLEY E. KELLIE, MD, MSc, AND JACOB A. BRODY, MD

Abstract: Sex-, race- and age-specific hip fracture rates were determined using Health Care Financing Administration data for Medicare-reimbursed hip fracture hospitalizations from 1980 to 1982. Rates were highest in White women, lowest in Black men, and intermediate in White men and Black women. Proportions of hip fracture patients dying during hospitalization and those discharged to nursing homes, respectively, were: White men (10.5%; 49%); Black men (9.3%; 32%); White women (5.0%; 54%); and Black women (8.2%; 30%). (*Am J Public Health* 1990; 80:326–328.)

Introduction

In 1986 in the United States, there were in excess of 250,000 hospital admissions for hip fracture.[1] Elderly individuals who sustain hip fractures experience increased morbidity[2–7] and mortality.[8–12] In an earlier paper, Farmer, *et al*,[13] reported that age-specific hip fracture rates were higher in White women than in White men, Black women, and Black men, but the differences among age-specific rates for White men, Black men, and Black women could not be estimated precisely.

In this paper we report age-, sex-, and race-specific hip fracture rates extended through age 85 years. In addition, we present findings for proportions of patients dying during hospitalization, and discharged to nursing homes, not previously reported for Blacks.

Methods

Numbers of Medicare-reimbursed hospitalizations for hip fracture in Illinois residents over 65 years of age were obtained from data collected by the Professional Standards Review Organization in Illinois during 1980, 1981, and 1982. The Uniform Hospital Discharge Format was used in the data collection, and the data tape was made available through the Health Care Financing Administration (HCFA). Hip fracture was defined according to the ninth revised International Classification of Diseases[14] categories 820.0–820.9: transcervical fractures, closed and open; pertrochanteric fractures, closed and open; and fractures of unspecified parts of the neck of the femur, closed and open. Populations at risk for hip fracture were obtained from the 1980 United States Census figures for the Illinois population by age, race and sex.

Mean numbers of hip fractures for 1980, 1981, and 1982 were used to calculate the sex-, race- and age-specific annual incidence rates for hip fracture. Miettinen test-based confidence intervals were calculated for the hip fracture relative risks.[15] Age-adjusted odds ratios for death and nursing home placement were determined using the Statistical Analysis System multiple logistic regression program.[16] Race- and sex-specific means for days of hospital stay were adjusted for age with the Statistical Analysis System linear regression program.[17]

Results

Age-group specific hip fracture rates were highest for White women, and lowest for Black men in all age groups after age 70 years (Figure 1). The rates in Black women are

similar to those in White men, and intermediate to those observed for White women and Black men. Hip fracture rates began to increase exponentially after age 70 years in White women, after age 75 in White men and Black women, and at approximately 85 years of age in Black men. Hip fracture rates in White women were approximately twice those in White men from age 65 to 85 years.*

In-hospital hip fracture death rates were highest for White men (10.5%), followed by Black men (9.3%), Black women (8.2%), and White women (5.0%). Age-adjusted odds ratios for death among hip fracture cases are shown in Table 1. After age-adjustment, in-hospital death rates were twice as high for White men as for White women. Black men had only slightly higher death rates than Black women.

The means for lengths of hospital stays were: Black men (28.0 days), Black women (28.2 days), White men (24.2 days), and White women (23.1 days). Discharge status of survivors is shown in Table 2. Both Black men and women were discharged to nursing homes less frequently than White men and women. After age-adjustment, the odds ratio for nursing home placement in White women compared with Black women was 2.70 (95% CI: 2.21, 3.30), and in White men compared with Black men 1.93 (95% CI: 1.16, 2.61).

Discussion

These data are consistent with earlier observations showing highest age-specific hip fracture rates for White women.[13] However, our findings also indicate higher age-specific rates in women than in men among both Blacks and Whites, although the sex difference occurred at older ages in Blacks than in Whites, as did the race-related differences. These findings are consistent with the age-, sex- and race-specific hip fracture rates recently reported for hip fracture hospitalizations in California.[18]

Black men and women may have lower hip fracture rates because, as adults, they exhibit higher levels of bone mass attained during growth and development.[19–25] In addition, race-related differences in the Vitamin D endocrine system suggest that Blacks are protected from the bone-resorptive effects of parathyroid hormone,[26] and reports of lower bone turnover rates in Blacks may result in slower rates of age-related bone mass than occurs in Whites.[27] The race difference in women is consistent with evidence that obesity is more common in Black women which may increase their extra-ovarian production of estrogen,[28] and that Black women may experience lower rates of menopause-associated bone loss than White women.[29]

While risk for falling, in addition to bone mass, influences hip fracture incidence,[30–32] the extent to which falling risk contributes to race- and sex-differences in hip fracture rates remains unclear. Elderly men are reported to fall less frequently than elderly women.[32] While Black women are reported to have greater muscle mass than White women,[33–35] it is not known if muscle mass acts independently of its documented influence on bone mass, to influence falling risk.

The finding of higher mortality rates in White men than in women is consistent with observations from earlier studies.[8–12] The most comparable race-specific mortality data were reported for small numbers of non-White hip fracture patients in which the risk for mortality at three months post hip fracture in non-Whites versus Whites was 1.5 (95% CI: 0.6, 3.6).[12] In addition to length of hospital stay, in-hospital mortality rates are also influenced by the numbers and severity of co-existing illnesses.[12] In the absence of comorbidity and severity of illness data in this analysis, interpretation of the in-hospital mortality data reported is difficult.

Hospital lengths of stay observed in this study are for the period prior to the implementation of the diagnosis-related group (DRG)-based prospective payment system (PPS), and are consistent with those reported by Fitzgerald, *et al*,[36] which also noted that the shorter lengths of stay after the PPS (12.6 days) were associated with fewer in-hospital physical

therapy sessions, poorer ability to ambulate on hospital discharge, and higher rates of discharge to nursing homes.

The finding of lower proportions of Black men and women discharged to nursing homes is consistent with race-specific national data for nursing home use.[37]

The Epidemiology of Vulvovaginal Candidiasis: Risk Factors

BETSY FOXMAN, PHD

Abstract: The effects of personal hygiene, sexual history, diet, and stress on the risk of vulvovaginal candidiasis were estimated from a case-control study of students attending a public university during 1986–87. Data from medical records and self-administered questionnaires were used to compare 85 cases to 1,245 other students using the Health Service, and to 113 subjects chosen from the total student population. Frequent sexual intercourse was the strongest risk factor (seven or more times a week versus none): OR = 4.3; 95% CI: 1.4, 12.9 (for cases versus Health Service controls). (*Am J Public Health* 1990; 80:329–331.)

Introduction

Vulvovaginal candidiasis, a common, irritating and frequently recurring infection, has been associated with broad spectrum antibiotic treatment, diabetes, and pregnancy.[1] Although factors such as diet high in sugar, using tampons or perfumed toilet paper, or wearing tight clothing are suspected to increase risk of vulvovaginal candidiasis,[1,2] few studies have examined these factors in a systematic fashion. In this study, I explored the relationships between personal habits, behaviors, and vulvovaginal candidiasis by analyzing a subset of data from a Health Service-based case-control study of urinary tract infection.[3]

Methods

Cases and controls were collected as part of a previously described study of urinary tract infection.[3] For that study, participants were recruited from women presenting with and without urinary symptoms to the University Health Service between September 1986 and December 1987. Prior to seeing a clinician, participants were given a self-administered questionnaire including questions about medical history, stress, clothing, diet, sexual activity, and birth control method during the past four weeks. The medical records of all participants recruited at the Health Service were reviewed to establish diagnosis and to confirm information on birth control method and history of other infections.

There were two control groups: women using the Health Service during the same time period as the cases (Health Service controls); and a sample stratified by year in school of 200 women enrolled at the University during January, 1988 (student population controls). Of these 200, 170 had complete and accurate addresses and 115 consented to participate. Student population controls completed essentially the same questionnaire distributed at the Health Service, but medical records were not reviewed.

Case and Control Definition

A case was defined as any woman who was recruited during a visit for which the diagnosis listed in her medical record was vulvovaginal candidiasis (n = 85). Health Service controls were women without a clinical diagnosis of vulvovaginal candidiasis recruited from the University Health Service. Population-based controls were limited to women who did not report current infection with either vulvovaginal candidiasis or a urinary tract infection. Both cases and controls were limited to non-pregnant women without urinary tract infection enrolled at the University.

Analysis

Exploratory analyses were conducted using multilevel contingency tables with both stratification and multivariate techniques to control for confounding.[4,5] Odds ratios (OR) and associated 95 percent confidence intervals (95% CI) were calculated from the logistic regression models as described by Schlesselman.[4] A separate model was fit for each factor of interest with age, frequency of sexual intercourse, number of previous infections with vulvovaginal candidiasis, and, for Health Service controls, month of enrollment, included as covariates. Related variables, such as birth control methods, were fit in a single model. All factors of interest were considered as potential confounders of other factors but only those variables that made a difference were included as covariates in the final models. For example, the OR for feminine hygiene use for cases compared to Health Service controls was calculated from a logistic regression model with presence of vulvovaginal candidiasis as the dependent variable, and age, frequency of sexual intercourse, number of prior infections with *Candida*, month of enrollment, and feminine hygiene use as independent variables.

Results

A total of 85 women met the study case definition; 1,245 Health Service and 113 population-sampled participants met the control definition. Study participants were similar to women students enrolled in the University with respect to year in school, age, ethnic group, and marital status. Cases and controls ranged in age from 17 to 72 (mean = 21.8 years). Age, year in school, and marital status were similar for cases and controls. Self-reported history of previous vulvovaginal candidiasis was common among both cases (77.7 percent) and controls (Health Service: 41.2 percent; student population: 19.6 percent). Most previous infections occurred within the past 12 months (cases: 74 percent, Health Service: 60 percent; student population: 62 percent).

When controlled for the confounding effects of age, frequency of sexual intercourse, and month of enrollment, women reporting one previous infection, compared to none, were about twice as likely to have a current infection (Health Service: OR = 1.55; 95% CI: 1.35, 1.78; population: OR = 2.06; 95% CI: 1.58, 2.69), and those with two infections about three times as likely (Health Service: OR = 2.39; 95% CI: 1.81, 3.16; population: OR = 4.25; 95% CI: 2.49, 7.25).

Cases were twice as likely as controls to have been sexually active during the past four weeks; the odds ratio increased with increasing frequency of sexual intercourse for both control groups (Table 1). However, having a new partner or engaging in sexual intercourse with multiple partners during the past four weeks showed no association

†Categories not mutually exclusive. Percents do not sum to 100, as some women used more than one method during the previous four weeks.

with *Candida*. Moreover, no one birth control method was associated with infection (Table 1).

Student population controls were more likely to use colored toilet paper and take tub baths than cases, but Health Service controls reported similar exposures to cases (Table 2). Other suspected risk factors, direction wiped following toileting, menstrual protection, use of feminine hygiene products and clothing showed little association with vulvovaginal candidiasis (Table 2). Diet and stress also showed no association.

Discussion

To my knowledge, no previous controlled study has reported a relationship between sexual activity and vulvovaginal candidiasis although case reports suggest a correlation.[1] Sexual intercourse might facilitate movement of *Candida* into the vagina and result in local minor trauma, creating conditions suitable for yeast to invade tissues. Some authors have suggested that *Candida* can be sexually transmitted;[6] however, in this study neither beginning a new relationship nor having multiple sexual partners in the previous four weeks was associated with candidiasis after controlling for frequency of sexual intercourse.

Although similar with respect to demographic variables to all University students, it is possible that women using the Health Service are a select group. They were more likely to be sexually active and use contraceptives than the student population controls. The resulting selection bias might decrease the observed associations between sexual activity, or variables related to sexual activity, and candida when cases are compared to Health Service controls. Further, Health

Service users may be more likely to have diseases associated with sexual activity and thus be more likely to adopt behaviors thought to limit infection. This may account for the differences in associations when cases are compared to student population rather than Health Service controls. Cases and controls completed the same questionnaires minimizing any misclassification with respect to exposure. Because case status was based solely on clinical diagnosis, undoubtedly some misclassification of disease occurred. However, the bias should have been at random, biasing the results toward no difference between groups.

This study showed a strong association between sexual intercourse and vulvovaginal candidiasis among non-pregnant women. Other suggested factors—wearing tight clothing, hose or synthetic underwear; type of menstrual protection; use of feminine hygiene sprays; and diet—were not associated with candidiasis. Most women with recurring vulvovaginal candidiasis tend to avoid all suggested risk factors,[1] which do not include sexual intercourse. Although these findings need confirmation, suggesting to women suffering recurring vulvovaginal candidiasis that they temporarily decrease frequency of sexual intercourse has more scientific basis than some of the other standard advice (wear cotton underwear), would do no harm, and might potentially avoid recurrence.

ACKNOWLEDGEMENTS

The author thanks the University of Michigan Health Service for their support of this study. Without the efforts of the triage nurses who distributed the questionnaires, the study would not have taken place.

Recurring Urinary Tract Infection: Incidence and Risk Factors

BETSY FOXMAN, PHD

Abstract: Urinary tract infection (UTI) is a common infection among young women, with a high recurrence rate. This study documents the six-month incidence of second UTI among a cohort of women with one initial UTI and the factors associated with recurrence. Among the cohort of 113 women, 30 (26.6 percent) experienced at least one culture-confirmed recurrence within the six months following initial infection. The presence of hematuria and urgency as symptoms of initial infection were the strongest predictors of second infection. Behavioral factors associated with initial infection (frequency of sexual intercourse, diaphragm use, and voiding after sexual intercourse) did not distinguish between women who would and would not experience a second UTI during the six-month follow-up period. (*Am J Public Health* 1990; 80:331–333.)

Introduction

Urinary tract infection occurs frequently among young women, with over one-fourth having a second infection.[1] Why otherwise healthy women with no known anatomical abnormalities have multiple recurrences is a subject of some controversy, although both host and agent characteristics have been suspected. However, most authors would agree with Kunin's statement that the risk of a second infection is greater than the first, and that the first "sets the stage" for recurring infection.[2]

Methods

All cases of first UTI among college women enrolled in a previously described case-control study* were eligible to participate in the follow-up study. A UTI was defined as the presence of significant bacteriuria (≥10,000 colonies of a single bacteria per milliliter urine) and one or more urinary symptoms: hematuria, dysuria, frequency, urgency, or suprapubic pressure. Urinalyses and urine cultures were performed on all women presenting with urinary symptoms using standard techniques.* History of UTI was assessed by review of medical records and self-report.

Prior to enrollment, participants completed a self-administered questionnaire which contained a consent form approved by the University of Michigan Institutional Review Board and questions on medical history, stress, clothing, diet, sexual activity, and birth control method. Responses to questions regarding birth control method, sexual activity, history of UTI, and demographics and the presence of UTI were confirmed by review of medical records. At the end of the six-months follow-up, participants' medical records were again reviewed to record the number and timing of UTIs treated.

Symptoms (frequency, dysuria, nocturia, urgency, hematuria, fever, chills, back or flank pain, and any other symptoms specified by the respondent), costs of treatment, measures of disease impact, and whether a woman had changed her health habits following the UTI were assessed via a self-administered questionnaire sent to all participants two weeks following enrollment.

Since bacteria normally found in the intestine cause the majority of UTIs in this age group, a woman may be

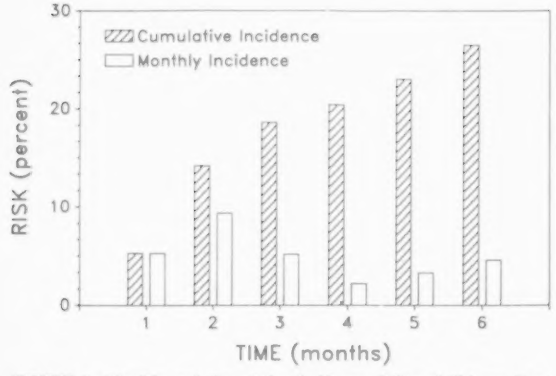

FIGURE 1—Monthly and Cumulative Incidence of Second Urinary Tract Infection (UTI) among a Cohort of 113 Women with One Prior UTI

re-infected with identical bacteria making it difficult to distinguish relapse from recurrence even in the presence of sophisticated bacteriologic techniques. As such techniques were not used in this study, I defined a recurrent urinary tract infection as the presence of ≥ 10,000 col/ml of a single bacteria and one or more urinary symptoms occurring at least two weeks after the initial infection. This may lead to some misclassification of outcome; however, as long as the classification is not associated with the exposure(s) of interest the resulting measures of association should be biased toward the null hypothesis of no difference.

The associations between hypothesized risk factors and repeat UTI were studied using multilevel contingency tables, with both stratification and multivariate techniques to control for confounding.[3] I calculated six-month cumulative incidences of UTI, risk ratios (RR), and Mantel-Haenszel summary RRs. Exact 95 percent confidence intervals (CI) were calculated around each RR using the method of Gart.[4]

A three-level symptoms scale, (0 = no hematuria or urgency, 1 = urgency alone, 2 = hematuria and urgency) was developed and used both as a dependent and independent variable in the analysis. When used as a dependent variable, I tested the hypothesis that the relationship was linear and the slope zero with a chi square test for trend.[5] Linear regression models with number of culture confirmed repeat UTIs and with the symptom scale as dependent variables were also fit to the data.

Results

The study cohort consisted of 113 women ages 17 to 39 (mean 21.3 years) with a first UTI. None of the participants had pyelonephritis, nor concurrent infection with gonorrhea, herpes, or chlamydia. The majority were White (83.8 percent), single (90.1 percent), and did not have a private physician (other than at the Health Service) within driving distance of their current residence (71.2 percent). Most had sexual intercourse during the four weeks prior to their first UTI (94.6 percent).

The six-month risk of a second UTI was 26.6 percent; the risk of a third UTI, 2.7 percent. Figure 1 shows the distribution of second infections; the median time to recurrence was approximately two months (56 days).

The presence of hematuria and/or urgency as symptoms of first infection was the strongest predictor of second infection (Table 1). Although the confidence intervals around the risk ratios include 1.0 (no difference), a significant relationship between symptoms and second infection was observed using a linear regression model including age as an independent variable (linear regression coefficient: 0.149, SE = 0.064). Other symptoms—fever, chills, flank or back pain, frequency, nocturia, or dysuria—were not associated with second infection.

Frequency of sexual intercourse, diaphragm use, and voiding around sexual intercourse were only weakly associated with second infection (Table 1). The trend in decreasing proportion of second infections with voiding after sexual intercourse is of interest (linear regression coefficient: −0.033; SE = 0.033).

Neither frequency of sexual intercourse, diaphragm use, nor voiding after sexual intercourse were associated with the presence of urgency and hematuria at first infection. However, increasing age was negatively associated with increas-

ing symptoms (linear regression coefficient: −0.012; SE = 0.013).

Discussion

In this study, factors observed to be associated with UTI in previous studies[6-9]—frequency of sexual intercourse, diaphragm use, and voiding after sexual intercourse—did not predict recurrence in the next six months. The strongest predictors were characteristics of the infection itself: the presence of hematuria and urgency. Indeed, the six-month risk of second infection was three times higher among women with both, compared to neither, symptom (13.6 percent vs 38.3 percent). This suggests that it is the characteristics of the bacteria causing the initial infection and the extent of infection which predict recurrence.

Since I depended upon medical records for report of recurrence in a fairly mobile population, the risk of second UTI was probably underestimated. Moreover, sophisticated bacteriologic techniques were not used, making it impossible to determine how a particular bacteria and associated virulence factors might set the stage for recurrence. However, the results imply that future studies should examine bacterial and host characteristics as well as health behaviors to better understand the etiology of recurring UTI.

In conclusion, among this cohort of college women with initial UTI, demographic and behavioral factors did not distinguish between women who would and would not experience a second UTI during the six-month follow-up period. The strongest predictor of second infection was the presence of hematuria and urgency as symptoms of initial UTI. Future studies should use consider both behavioral and bacterial characteristics as potential determinants of recurring UTI.

Potential for Lyme Disease in Maine: Deer Survey of Distribution of *Ixodes dammini*, the Tick Vector

ROBERT P. SMITH, JR, MD, MPH, PETER W. RAND, MD, AND ELEANOR H. LACOMBE, BS, MT (ASCP)

Abstract: A survey of deer brought to tagging stations at 24 sites in Maine revealed the presence of the deer tick, *Ixodes dammini*, on 5.1 percent of deer. Ticks were found almost exclusively on deer from southwest coastal sites in the state. The potential for endemic Lyme disease in coastal Maine merits further study. (*Am J Public Health* 1990; 80:333–335.)

Introduction

The current geographic range of *Ixodes dammini*, the principal vector of Lyme disease in the eastern United States, is incompletely established. Continued spread of *I. dammini* in coastal New England accounts for new foci of Lyme disease in previously non-endemic areas.[1,2] Recent studies document the rapid rise of Lyme disease prevalence in some areas following colonization by the deer tick.[1] As public education remains the primary means of prevention of Lyme disease, knowledge of the regional distribution of the vector ticks enables targeted surveillance and focused public health interventions. Prior to 1985, there were no records of *Ixodes dammini* from Maine.* Although Maine has been considered a non-endemic area for Lyme disease, infected *I. dammini* were recently reported from one coastal Maine site[3] and *I. dammini* have been found on a deer shot in a northern inland site.[4] Three locally acquired seropositive cases of Lyme disease meeting Centers for Disease Control (CDC) criteria were reported to the Maine Bureau of Health between 1986 and 1988. We undertook a survey of ticks on deer brought to Maine tagging stations in 1988 to further describe the distribution of *I. dammini* at its northeastern limit in the United States.

Methods

Twenty-four deer tagging stations were selected for surveillance throughout Maine in consultation with state

Inland Fisheries & Wildlife officials. Sites were chosen on the basis of high deer registrations during the previous hunting season, their proximity to representative coastal and inland habitat, and their accessibility to survey teams.

Volunteers including college biology students and their instructors, physicians, and public health professionals, and personnel from Inland Fisheries & Wildlife participated in two weekend surveys October 29 and November 5, 1988. Each team was supplied with a study protocol, an information sheet for hunters, data forms for each deer examined, 6 ml screw-top polyethylene specimen bottles with 70 percent alcohol, fine-point plastic tweezers, and rubber gloves. After obtaining permission from the hunter, each deer was examined for five minutes in a search for adult ticks that included the face, neck and ears of each deer. Ticks were removed with tweezers placed as close to the skin as possible. For each deer, the quantity and location of the ticks found, the times of the kill and of the examination, and the topography and vegetation of the kill site were recorded.

Type specimens of ticks were sent for species confirmation to Dr. J. E. Keirans, Department of Entomology, Smithsonian Institution, Washington, DC.

Results

Seventy volunteers visited 24 tagging stations at least one day of the hunting season. Two hundred and thirty-seven deer (141 male, 68 females, 28 sex unrecorded) taken in 66 towns, townships and plantations, including one island community, were examined. Twelve deer (5.1 percent) harbored *Ixodes dammini* ticks. A total of 33 ticks (all adults) were collected with a range of 1 to 11 ticks per infested deer. Ticks obtained from the hides of three freshly killed deer at a southwest coastal site are also included in the total. The average time of the examination of deer after the kill was 3.5 hrs (range, 0.5–46.5 hrs). Not included are time data from one island community where deer were examined one to three days after being tagged. Ten deer were found to harbor the "winter tick," *Dermacentor albipictus*. No other ectoparasites were obtained.

With the exception of one tick, all *I. dammini* were obtained from deer in the southwest coastal areas of Maine (see Figure 1). No ticks were found on deer from the one island studied. No association could be made between type of habitat at kill sites and deer infestation by *I. dammini* ticks.

Discussion

This study documents the presence of *Ixodes dammini* on deer from the southwest coast of Maine and a relative paucity of ticks from deer in inland areas. The habitat of southwest coastal Maine is similar to that in some other coastal New England areas with a high prevalence of Lyme disease, and it is characterized by deer herd densities as high as 20–50 per square mile. Although infection rates of ticks collected in this study were not determined, 12 percent of a small sample of adult and nymphal deer ticks from Acadia National Park harbored *Borellia burgdorferi*.[3] An infection rate of at least 10 percent has characterized other New England sites of *Ixodes dammini* colonization.[4,6] Although tick density on the deer examined was low relative to highly endemic sites,[7] the degree of risk for transmission of this zoonosis in southwest coastal Maine deserves further study. All three cases of endemic seropositive Lyme disease reported in Maine through 1988 were believed to have been acquired in this region. As there are no records of *I. dammini*

FIGURE 1—Number of Deer upon Which *I. dammini* Were Found versus Total Deer Examined in Four Geographical Areas in Maine

or Lyme disease in Maine prior to 1985, we believe that *I. dammini* has appeared here recently.

The sensitivity of deer surveys for the determination of presence of *Ixodes dammini* is unknown. The method of examination used, rigorousness of search, and training of personnel could alter its effectiveness. Reporting of other ticks on the deer (i.e., *D. albipictus*) is considered an indicator of the sensitivity of the search, but the expected prevalence of *D. albipictus* on northern New England deer is not known. A recent study of 370 deer in Vermont by trained wildlife personnel documented only two *Ixodes dammini* and no other ticks, although other ectoparasites were noted.** Comparative information of the effectiveness of deer surveys, dog seropositivity studies, and other methods of surveillance is needed. Our study is limited by marked differences in the number of deer available for examination at many tagging stations. The low number of deer examined in most inland sites and our inability to canvass all areas of the state systematically makes conclusions regarding the full range of *Ixodes dammini* in Maine premature. Nevertheless,

**Mamolen M: Personal communication. Department of Health, State of Vermont.

the results of this deer survey coupled with the known ecology of southwest coastal Maine point to an emerging zoonosis in this area with potential public health importance.

HRSA Health Care Program for the Homeless Reaches Its Legislative Goals

In a report to Congress on January 3, 1990, the Health Resources and Services Administration (HRSA) reported that its health care for the homeless program had been "successful in reaching its legislative goals." The report, which covered activities in calendar year 1988, was the first annual report on the program and noted the following:

- Within four months after signing of the authorizing legislation, the Steward D. McKinney Homeless Assistance Act, HRSA awarded $44.5 million in grants to 109 health care projects for the homeless in 43 states, the District of Columbia, and Puerto Rico.
- The 109 projects provided health care services to more than 231,000 homeless persons.
- Forty percent of the homeless persons served were children and their parents (living as a family unit) or homeless/runaway youths.
- Fifteen percent of those served were children ages 14 or younger.
- Thirteen percent of pregnant homeless females treated were teenagers.
- Sixty percent of persons served were minorities: 42 percent Black, 10 percent Hispanic, and 8 percent Native American, Asian, or other non-White.

The report concluded by saying, "The health care for the homeless program has demonstrated that the federal government, in concert with local communities, can bring health care services to homeless persons within a short period of time." Nursing Conference on Homelessness Scheduled May 3–4, 1990

A two-day forum for nurses and other health professionals involved in health care for the homeless projects will be held under sponsorship of a HRSA-supported project at State University of New York, Buffalo, May 3–4, 1990. Topics of the conference will include issues related to homeless children and mental health. For information about the conference, entitled "Homelessness: An Issue for the Nineties," contact: Continuing Nurse Education, School of Nursing, 14 Kimball Tower, SUNY at Buffalo, 3435 Main Street, Buffalo, NY 14214. Tel: 714/831-2391.

AIDS TREATMENT NEWS

Published twice monthly by John S. James, *AIDS Treatment News* reports on experimental and standard treatments, and examines the ethical and public-policy issues around AIDS treatment research and treatment access.

"Without any doubt, John James is one of the three or four most influencial writers on the AIDS epidemic in America today. His meticulously researched reports in *AIDS Treatment News* have allowed tens of thousands of his readers to literally gain a new grasp on life. More significantly, his on-going analysis of the failings of the government regulatory and research establishment inspired much of the nation's AIDS activism today and continues to inform both lay and expert readers about the challenges ahead. His work holds a place of honor in the history of the AIDS epidemic."

– Randy Shilts, National Correpondent, *San Francisco Chronicle*;

Human Immunodeficiency Virus Seropositivity among Members of the Active Duty US Army 1985–89

PATRICK W. KELLEY, MD, MPH, RICHARD N. MILLER, MD, MPH, ROBIN POMERANTZ, MS, FRANK WANN, MS, JOHN F. BRUNDAGE, MD, MPH, AND DONALD S. BURKE, MD

Abstract: Between October 1985 and June 1989, most active duty US Army soldiers were screened for human immunodeficiency virus (HIV) antibody. Of 648,032 screened soldiers in this analysis, 1,588 were HIV-antibody positive. In a multivariate analysis, correlates of positivity included: *age* [Adjusted Odds Ratios (ref <20 years) = 20–24 years, 3.7; 25–29, 9.3; 30–34, 15.7; ≥35, 15.9]; *being male*, [4.2]; *being Black or Hispanic (vs white)* [3.7 and 3.0, respectively]; *being single (vs married)* [3.8]; *assignment to an HIV endemic location* [1.7], and *having a medical occupation* [2.7, 2.7, and 2.6 for negligible, low, and high blood exposure professions, respectively]. Seropositivity rate ratios for medical vs non-medical personnel were 0.7 [95% CI = 0.4, 1.4] for females and 2.9 [95% CI = 2.5, 3.3] for males. For male medical personnel, being single (vs married) correlated strongly with antibody positivity [prevalence ratio = 3.4, 95% CI = 2.6, 4.6]. Excess HIV risk among medical personnel appeared largely attributable to factors other than occupational exposures. (*Am J Public Health* 1990; 80:405–410.)

Introduction

Effective programs to prevent the spread of human immunodeficiency virus (HIV) infection in the general population require the identification of target populations for intense health education and voluntary test-linked counseling.[1–4] Although much is known about the epidemiology of the acquired immunodeficiency syndrome (AIDS), the end stage of HIV infection, the value of this information for educational purposes is limited by the fact that AIDS cases generally reflect transmission risk factors that were operating years ago.[5,6] Prevention programs must reflect HIV infection-transmission patterns operating today and those likely to emerge in the near future. Prevalence and incidence surveys of generally healthy populations can help identify populations for targeted HIV prevention education.

Except for the national blood-donor screening programs, military HIV screening programs currently provide the only HIV seroprevalence data on large cross sections of the US population. Several papers have previously summarized the demographic risk factors for military recruit applicants, a group largely between the ages of 17 and 24.[7–9] In that population, the cumulative seroprevalence is 1.4/1,000 although over time the monthly rates have progressively dropped to below 1.0/1,000, a phenomenon that probably reflects self-deferral of potential applicants who either know from other sources or suspect that they are seropositive. Among recruit applicants, seropositivity is several-fold higher in Blacks, Hispanics, and males. Similar findings have been noted for members of the US Army Reserve Components.[10]

This paper, the largest detailed summary of military HIV demography published to date, expands on the recruit applicant data by focusing on active duty soldiers, a somewhat older group of persons who are more likely to be married and to have had substantial employment experience.

Dr. Miller and Dr. Brundage are also with the Division of Preventive Medicine at Walter Reed; co-authors Pomerantz and Wann are with SRA Technologies, Inc., Alexandria, Virginia; Dr. Burke is with the Division of Retrovirology at Walter Reed. This paper, submitted to the Journal June 5, 1989, was revised and accepted for publication November 8, 1989.

Editor's Note: See also related editorial p 401 this issue.

Methods

Population

On October 24, 1985 the Secretary of Defense directed that all 2.1 million active-duty US service members undergo mandatory HIV education and antibody screening.[11,12] This objective was addressed through a variety of programs that included mass screening of military units, screening prior to overseas deployment, blood donor testing, sexually transmitted disease (STD) clinic patient screening, case-contact tracing, and testing for clinical reasons. In 1988, the unit screening program was largely replaced by a birth month screening program designed to ensure that each soldier is tested at least once every 24 months.

HIV Testing

Sera collected as part of the mass screening program were tested with a licensed whole-virus lysate enzyme-linked immunosorbent assay (ELISA). This work was largely done at either a central civilian contract laboratory (Damon Laboratories, Irving, TX) for soldiers assigned to the continental US, Alaska, or Panama; at the 10th Medical Laboratory, Landstuhl, Germany for soldiers stationed in Europe; or at Tripler Army Medical Center for soldiers in Hawaii and the Far East. Positive samples were immediately retested in duplicate with the ELISA.[13] Repeatedly positive samples from all screening laboratories were tested for reactivity with HIV proteins by the Western (immune) blot method by the civilian contract laboratory.[14] From October 1985 until May 1987, specimens were classified as positive if antibodies to HIV-encoded protein GP41 and/or protein P24 plus P55 were detected.[15] In May 1987, the Association of State and Territorial Public Health Laboratory Directors criteria for a positive blot were adopted: at least two out of three of the major HIV protein bands P24, GP41, and GP120/160. Soldiers found positive on the initial Western blot had a second specimen drawn for verification purposes. A detailed Army-administered quality-assurance program characterized by monthly on-site laboratory inspections and specific performance criteria (including the successful analysis of both in-house controls and blind and unblinded panels) has been described elsewhere.[15]

Statistical Analysis

Because the Army population is undergoing constant turnover with only HIV-seronegative applicants allowed to enter and because during the period of data collection

HIV-antibody positive soldiers have separated at a significantly faster rate than seronegative soldiers, this analysis, for reasons of clarity and reference, is confined to those soldiers on active duty when the program was just beginning, specifically on June 30, 1986. Laboratory results, social security number, first four letters of the last name, and test date were keyed onto computerized data files and merged with an abstracted copy of the June 30, 1986 active duty Army personnel file as supplied by the Defense Manpower Data Center, Monterey, CA. For soldiers with more than one test result recorded, only their most recent test was retained in the analysis data set. Antibody positivity was considered verified if an individual was reported by a separate clinical reporting system as HIV-infected (96.2 percent of those potentially considered positive were clinically verified as such) although in 22.9 percent of the cases clinical verification was based only on the documentation of an individual having had multiple positive HIV Western blots on separate specimens. Only soldiers verified to be HIV-infected prior to August 3, 1989 are considered HIV-infected for this analysis.

Seropositivity rates were calculated as both centrally screened and overall rates. The centrally screened rate is defined as the number of antibody positive soldiers who were reported as having been screened through the three centralized laboratories listed above divided by the total number of soldiers reported as screened by those laboratories.

Many soldiers found to be antibody positive were initially tested through testing activities conducted outside of the centralized testing laboratories (e.g., blood bank and some STD clinic screening). These individuals often were exempted from subsequent mandatory testing done by the centralized laboratories. The overall rate is based on a numerator that includes all antibody-positive active-duty soldiers who were in the Army on June 30, 1986 divided by the number centrally screened plus the number of positive soldiers not reported from the central laboratories. The centrally screened rate is a significant underestimate of the true rate because only 79 percent of the eligible antibody positive soldiers ever had a centralized screening test result reported. The overall rate is felt to be a modest overestimate because the denominator excludes a small though unquantifiable number of seronegative soldiers who either were tested but did not have a negative test reported or who were not centrally screened but were antibody negative in adjunct screening programs, such as blood bank and clinical screening. Some negative ELISA results from blood bank and clinical screening were not captured for epidemiologic purposes since not all of the adjunct screening was done by one of the three centralized HIV testing laboratories.

Because of centralized Western blot testing, positive blots from all testing programs were captured in an extremely complete fashion. For the most part, only overall rates and measures of effect based on overall rates will be described in the text since the overall rates are felt to best reflect the true rates. In the analyses of prevalence by occupation, broad occupational clusters were defined according to Army regulation, with minor modifications.[16] For the analysis of prevalence among medical personnel, the blood exposure groupings with minor modifications were those of Gardner, *et al.*[17]

To demonstrate the effect of a possible risk factor, seropositivity rate ratios with 95% confidence intervals were calculated.[18] In bar graphs, 95% CIs are based on the Poisson distribution. The main effects logistic regression analysis was performed with the Stepwise Logistic Regression (PLR) procedure of the BMDP Statistical Software Package (University of California at Los Angeles). All listed variables were forced into the model. Adjusted odds ratios were calculated by using logistic regression parameter estimates.[19] Confidence intervals for odds ratios and estimates of their statistical significance were derived from standard errors of the parameter estimates.[19]

Results

As of July 27, 1989, centrally screened results have been received for 647,700 soldiers out of the 763,675 individuals in the June 30, 1986 active-duty Army personnel file abstract. Demographically, this 84.8 percent sample (Table 1) constituted a representative sample of the whole Army. Three hundred and thirty-two soldiers who were verified as antibody positive but not reported as having been centrally screened were added to the analysis file. Of the 115,643 June 30, 1986 cohort soldiers without a documented HIV test result, 72 percent had separated from the active Army by December 30, 1988; 4 percent were accessions who had screened negative as part of the recruit-applicant screening instituted on October 1, 1985. The 28,863 remaining active-duty soldiers for whom valid test results were unavailable, were demographically similar to those tested based on race but women, married persons, officers and those at the extremes of the age spectrum appeared to be more likely not to have had a test reported.

Overall Seropositivity

The centrally screened seropositivity was 1.9/1,000 based on the 1,256 verified positive soldiers who had been centrally screened. The overall rate based on the 1,588 June 1986 cohort positives was 2.5/1,000. Of the 1,588 cohort soldiers who were verified as HIV antibody positive as of

TABLE 1—Characteristics of the Sample HIV Screened

Characteristic*	Army Population	Proportion of Army	Sample Population	Proportion of Sample
Age (years)		%		%
<20	78,543	10.3	66,430	10.3

≥10	185,311	24.3	159,161	24.6

*As recorded in June 30, 1986 military personnel file.

August 3, 1989 the reported sources of identification were: 809 (50.9 percent) through unit or birth month screening, 136 (8.6 percent) through clinical evaluations, 112 (7.1 percent) through pre-deployment screening, 101 (6.4 percent) through blood donor screening, 59 (3.7 percent) through STD clinic screening, 48 (3.0 percent) through self-referral, 17 (1.1 percent) through contact tracing, and 306 (19.3 percent) through other or unspecified sources.

Age

Antibody positivity varies significantly with age. For soldiers less than 20 years old at their most recent available test (a group heavily preselected to be negative by recruit-applicant testing), the overall rate was 0.5/1,000. Thereafter, there was a steady progression from an overall rate of 1.8/1,000 in those aged 20–24, to 3.1/1,000 in those 25–29 and to 3.4/1,000 in those 30–34. The rate among soldiers older than 34 drops to 2.2/1,000. A similar pattern was observed in the centrally screened rates.

Race or Ethnic Group

Soldiers who were Black or Hispanic had an overall seropositivity of 5.1/1,000 (900 cases) and 4.0/1,000 (95 cases), respectively. The HIV infection prevalence rate ratios compared to White soldiers were 4.0 [95% CI = 3.6, 4.4] for Blacks and 3.2 [95% CI = 2.5, 3.9] for Hispanics. Across age strata, Whites had a relatively flat prevalence trend; Blacks and Hispanics both showed a rise through the early thirties and then a fall (Figure 1). HIV infection would appear to be unevenly distributed among subsegments of the Hispanic population. The seropositivity rate for Hispanic soldiers with a home of record listed as Puerto Rico, New York, or New Jersey, a group assumed to be largely of Puerto Rican descent, was 5.6/1,000. In contrast, the Hispanic soldiers with a home of record in states along the Mexican border (California, Arizona, New Mexico, Texas) had a rate of 2.2/1,000 (PR = 2.5, 95% CI = 1.5, 4.3).

Sex

There were 1,516 verified positive cohort men, yielding an overall rate of 2.6/1,000. The corresponding female rate, based on 72 positive women, was 1.1/1,000. The crude male:female seropositivity rate ratio was 2.3 [95% CI = 1.8, 2.9]. Male:female overall rate ratios by race/ethnic group were 2.5 for Whites [95% CI = 1.5, 4.0], 3.0 for Blacks [95% CI = 2.3, 4.0], 2.1 for Hispanics [95% CI = 0.7, 6.7], and 3.1 for others (2 female cases). The overall rates in Black and Hispanic females were 1.9/1,000 (49 cases) and 1.9/1,000 (3 cases), respectively. The Black female rate exceeded the 1.3/1,000 overall rate in White males [RR = 1.4, 95% CI = 1.0, 1.9]. Age-specific male:female ratios did not show any definite trend across age strata (Table 2).

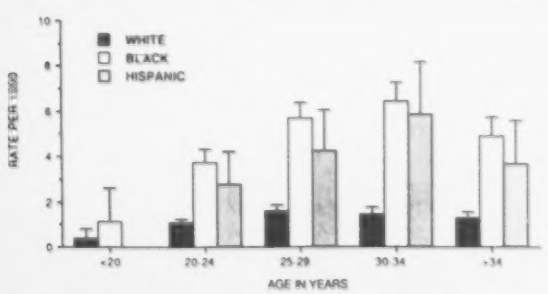

FIGURE 1—Overall HIV Seropositivity Rates and Upper 95% Confidence Interval Bounds for Active Duty US Army Personnel Stratified by Age and Race/Ethnic Group

Marital Status

Among the 1,588 cases, 639 were married, 878 were single, and 71 were no longer married, indicating that 44.7 percent of the cohort cases are or had been married based on the June 30, 1986 file. Compared to married soldiers, the HIV infection prevalence ratios for single soldiers and for those no longer married were 1.9 [95% CI = 1.7, 2.1] and 1. 8 [95% CI = 1.4, 2.3], respectively. Whereas overall rates were quite similar for married and single soldiers in the youngest age strata, single soldiers over 34 years of age had an overall prevalence rate that was 10.8 times that found in married soldiers in that stratum (Figure 2). Among White and Black soldiers, the rate ratios for single soldiers relative to married soldiers were 2.1 [95% CI = 1.8, 2.5] and 2.1 [95% CI = 1.8, 2.4], respectively. In contrast, the rate ratio for single Hispanic soldiers compared with their married counterparts was 1.1 [95% CI = 0.7, 1.7]. For males the overall single and married rates were 3.7/1,000 (844 cases) and 1.8/1,000 (607 cases), respectively. Among females the single (34 cases) and the married (32 cases) rates were both 1.1/1,000.

To explore the effects of age on estimates based on female marital status, female rates were directly age adjusted using the total male age distribution. The adjusted female rates were 1.2/1,000 for singles and 0.9/1,000 for marrieds.

Rank and Education

Based on 1,447 cases, the overall seropositivity rate for enlisted soldiers was 2.6/1,000. Warrant officers had an overall rate of 0.9/1,000 (12 cases) and commissioned officers an overall rate of 1.6/1,000 (129 cases). Within White, Black, and Hispanic groups, officer to enlisted prevalence ratios did not vary significantly (data available on request to author). Non-college graduates (less than 4 percent of soldiers in this cohort had not completed high school) had an overall rate of 2.6/1,000 (1,400 cases) in contrast to a rate of 1.9/1,000 (183 cases) for college graduates.

Occupational Category

HIV infection is distributed quite unevenly across job clusters (Table 3). Because health care workers had an elevated rate and because the potential for acquisition of infection in the course of performing job-related functions has been documented, several analyses were undertaken to better understand the source of risk for these individuals. Rate ratios comparing prevalence estimates for 42,697 health care providers [72.4% male] and 605,286 non-medical personnel [91.4% male] were 0.7 [95% CI = 0.4,1.4] for females and 2.9 [95% CI = 2.5, 3.3] for males. For male medical personnel being single [vs married] was a major correlate of

TABLE 2—US Army HIV Testing Overall Seropositivity Rate Estimates by Age and Sex

positivity [prevalence rates = 3.4, 95% CI = 2.6, 4.6]. Among single medical males over the age of 34, the seropositivity ratio relative to their married counterparts was 15.9 [95% CI = 9.3, 27.3]. Rate ratios for male medical staff with high- and intermediate-level blood exposure relative to male care providers with minimal blood exposure were 0.9 [95% CI = 0.5, 1.5] and 1.1 [95% CI = 0.7, 1.6], respectively.

Multivariate Analysis (Adjusted Odds Ratios)

To control for the simultaneous effect of many mutually confounding factors, a main effects logistic regression model was constructed using the variables in Table 4. To reduce the preselection effect of recruit-applicant screening which started in October 1985, only soldiers with at least 10 months of service as of June 30, 1986 were included in the model. Noteworthy changes in odds ratios brought about by multivariate adjustment included the less obvious decline in risk for the oldest soldiers, the increased risk for men relative to women (adjusted OR = 4.2) and for singles relative to married soldiers (adjusted OR = 3.8). Adjustment significantly brought down the odds ratios associated with increasing length of service. The odds ratios by race/ethnic group, endemicity group, and medical blood exposure category were not significantly changed by the adjustment.

TABLE 4—Main Effects Multiple Logistic Regression Model for HIV Infection in the US Army

Variables	Crude Odds Ratio	Adjusted Odds Ratio	95% Confidence Interval
Age (vs <20)			
20–24	3.5	3.7	1.7–8.4
25–29	5.4	9.3	4.1–21.1
30–34	5.6	15.7	6.9–35.8

Discussion

This analysis summarizes one of the largest population-based HIV antibody surveys undertaken to date. Although the observations are not directly generalizable to the 15 to 50 year old segment of the US general population due to various biases including the presumed underrepresentation of intravenous drug abusers and homosexuals in the military, the above results support the findings of other studies that HIV infection is an important issue for Black and Hispanic communities and for females.[7,20–23] The data appear to reasonably represent the people in the US Army on June 30, 1986. The entry and separation of over 100,000 people from the active component of the US Army each year plus the worldwide mobility of that population did not allow an HIV antibody screen to be completed on all members of the June 30, 1986 cohort.

The prevalence trend by age was similar to that noted for military recruit applicants and notable for a peaking in the late 20s and early 30s before tailing off in the mid-30s.[7] This trend in antibody positivity peaks several years before the peak described for AIDS cases. There are several possible explanations for the HIV antibody age pattern. First, those inclined to engage in risk behaviors may tend to moderate the intensity of their risk behaviors with age. Since the HIV virus has only been endemic in the US for an estimated 10–15 years, older soldiers may have passed through a period of more frequent risk taking before HIV was a significant presence. Second, older soldiers are more likely to be career soldiers than are those in the younger age strata. Soldiers who aspire to a military career and who have successfully adapted to the military environment (as suggested by many years of service) may be less inclined to practice some risk behaviors such as intravenous drug abuse and homsexuality because the practice of these behaviors is contrary to military policy. Since the early 1970s, random urine drug screens have been a regular occurrence in the Army, making even the covert use

of illicit drugs a risk to a soldier's career. After adjusting for marital status, length of military service, and other variables in the multiple logistic regression model, there is a steady increase in risk with age. Most importantly, however, these data suggest that significant risk of HIV infection begins in the late teens/early twenties and continues through the young adult period.

The observation that Black and Hispanic soldiers, even in the multivariate analysis, are at a three-to-four fold increased risk of being infected is consistent with civilian data.[7,20] The significant difference in prevalence trends by age for Blacks and Hispanics in contrast to Whites is again striking. A relatively flat prevalence trend for Whites and a dramatic rise and fall for Blacks and Hispanics may reflect a more rapid recognition of the HIV threat and its consequences on the part of Whites. The 2.5 fold increased risk of positivity for Hispanic soldiers with a home of record documented as Puerto Rico, New York, or New Jersey versus that for Hispanic soldiers with Mexican border state homes is reflective of Selik's finding that AIDS incidence appears to be higher in Hispanics of Puerto Rican descent than among other Hispanics.[24] Unfortunately, data on the risk behaviors directly responsible for the infections are not available to the authors. The observation that 50.4 percent of the 995 largely asymptomatic infected Black and Hispanic soldiers and 44.9 percent of the 536 largely asymptomatic White soldiers had at least seven years of service supports the impression that in the majority of cases the infection was acquired while the soldiers benefited from the economic, occupational, and social stability of a military environment. The fact that risk for both White and Black officers was similar to that of their enlisted counterparts further argues against a major role for current socioeconomic status in this military population.

As with all epidemics, the propagation of this epidemic depends on complex interactions among the agent, environment, and host. In the same way that high HIV prevalences (the agent-endemicity factor) among homosexual men tend to make sex acts (the behavioral-environment factor) more risky than similar acts among heterosexuals in a low HIV prevalence population, so too may risk activities in high prevalence minority populations lead to more infections than they might in lower prevalence communities. Although the data are inconclusive, race/ethnic differences in susceptibility (the host factor) to infection may be contributory factors also.[25–27]

In contrast to the 8:1 male:female AIDS case ratio in the US during the first half of 1989, the HIV infection prevalence ratio in these data is 2.4:1 (adjusted OR = 4.2:1 in multivariate analysis).[28] The prevalence ratio is similar to that reported for military recruit applicants.[7] In teenaged military recruit applicants (J. Brundage, unpublished data) and among people in the African HIV epidemic, the male-to-female ratio approximates 1:1.[21] Male:female prevalence ratios do not differ by race, but it is important to note that in the Army, the rate for Black and Hispanic women is 1.5 times higher than that found in White men, supporting the conclusion that women, particularly of racial/ethnic minorities, need special emphasis in prevention efforts. The marital status information further supports efforts to provide prevention education beyond single homosexual men. Although the marital status data do not allow any statement about the responsible risk activity, it shows that 45 percent of infected Army personnel are or were married. It would be reasonable to assume that most of these people participated in heterosexual sex at least some of the time and that many otherwise risk-avoiding heterosexuals were contacting the virus. One report of risk factors in a population of 57 US Army HIV-positive soldiers noted that 77 percent were heterosexually active, including 31 soldiers who said they were bisexual.[29] Centers for Disease Control AIDS data indicate that about 26 percent of reported AIDS cases are heterosexuals, although it is clear that most of these heterosexuals did not acquire their infections through sexual activity.[20]

Regarding risk by occupation, data presented here are consistent with other published estimates of the low risk for occupational acquisition of HIV infection in the medical setting.[30,31] The observations that excess risk for those in medical occupations appeared to be confined to males and that prevalence was not correlated with levels of occupational blood exposure are consistent with the conclusion that risk in Army health care personnel is largely due to factors other than occupational exposures. The logistic regression analysis also supports this and a comparable analysis of Army Reserve component data comes to a similar conclusion.[32]

The repeated testing of all active duty soldiers is allowing not only the ascertainment of antibody prevalence but also the current annual incidence of seroconversion. The first of these analyses for the period October 1985 to October 1987 identified 90 seroconvertors for a rate of 0.77 per 1,000 persons per year.[33] Current seroconvertors are carefully studied to ascertain potential shifts in transmission patterns since the design of prevention programs should reflect not only the transmission patterns in effect 10 or more years ago, but also recognize the role of emerging risk groups as the infection continues to spread, although probably more slowly, through initially unemphasized segments of the population.

NCHS Survey: Characteristics of Persons Dying from Stroke

Cerebrovascular disease—or stroke—is the third leading cause of death in the United States, accounting for almost 150,000 deaths in 1986. The National Center for Health Statistics conducted a special survey based on a sample of such deaths among those 25 years of age and over which occurred in 1986. The survey analyzed the health and other care received in the last year of life and source of payment, health practices and behaviors, health status, and social and economic characteristics of those who died from stroke. These data will be used in disease prevention programs and to plan adequate health and support services for those with cerebrovascular disease. The major findings include:

- Nearly 70 percent of those who died from stroke were over the age of 75. Less than half of the deaths from all other causes occurred to those 75 years of age and over.
- More women than men died from stroke, 60 to 40 percent, respectively. Women were about three times more likely to be widowed at the time of death and only one-third as likely to be currently married.
- Most adults who died in 1986 had seen a physician five times or more in the year prior to death. Persons dying from stroke were more likely to have no physician visits or fewer than five visits; and to have resided in an institution during the year prior to death.
- Medicare was the primary source of payment for health care in the last year of life for most causes of death, including stroke.
- A larger proportion of those dying from stroke than from all other causes were reported to have hypertension.

The Quality of Ambulatory Care in Medicare Health Maintenance Organizations

SHELDON M. RETCHIN, MD, MSPH, AND BARBARA BROWN, PHD

Abstract: The quality of ambulatory care received by Medicare recipients who enrolled in health maintenance organizations (HMOs) was compared to the care received by fee-for-service (FFS) Medicare recipients, in a quasi-experimental, non-randomized design. Both samples were drawn from the four major geographic areas in the country, and included two types of HMO practices: staff/group models, and independent practice associations (IPAs). A panel of expert physicians developed criteria for evaluating ambulatory care, and medical record abstractions using these criteria were performed on 1,590 outpatient records: 777 FFS and 813 HMO (441 staff/group, 372 IPA). While individual items of medical histories and physical examinations were performed most often for staff/group HMO patients and least often in FFS patients, odds ratios (OR) for performance in staff/group HMO patients were particularly large for health maintenance items: tonometry (OR = 8.4), mammography (OR = 2.7), pelvic examination (OR = 5.3), rectal examination (OR = 2.9), fecal occult blood test (OR = 3.3). The results suggest that recommended elements of routine and preventive care are more likely to be performed for Medicare enrollees in staff/group HMOs than in FFS settings. (*Am J Public Health* 1990; 80:411–415.)

Introduction

Due to the rising costs of delivering health care to Medicare recipients, federal cost containment measures have been initiated. Among these initiatives, the use of prepaid care strategies has received increased attention. In 1982, the Health Care Financing Administration began a demonstration program of prepaid health care for Medicare recipients. The 27 participating health maintenance organizations (HMOs) provided comprehensive care, received prospective monthly payments for the enrollees, and assumed the financial risk of their complete health care. The purpose of the program was to show whether contracts with HMOs for Medicare recipients' health care could both reduce costs effectively and also maintain current standards of care. Since the demonstration program began, optional Medicare enrollment in HMOs has been extended, and there are now about one million Medicare enrollees in more than 100 separate HMOs.

Since HMOs reduce the cost of care mainly by replacing hospitalizations with less expensive ambulatory care, utilization rates of their enrollees have been observed to fall to as low as half the rates of Medicare recipients in traditional care arrangements.[1,2] Although the number of ambulatory visits in prepaid systems of care does rise to compensate for the reduction in hospitalizations, it is possible that such increases may strain the resources on which elderly HMO enrollees depend to manage their disabilities. Multiple chronic illnesses are the rule and many have significant functional limitations; outpatient management of elderly persons thus requires considerable time and effort. Hence, misgivings exist as to whether financial constraints, under prepaid systems like HMOs, may lead physicians to compromises that reduce the quality of outpatient care elderly persons need.[3,4]

To study how prepaid reimbursement affects the care Medicare patients receive in HMOs, the federal government funded the National Medicare Competition Evaluation. This comprehensive study examined not only the effectiveness of prepaid care in cutting Medicare costs, but also its effects on patient satisfaction with the care,[5] and whether HMO Medicare patient care matched the quality of that received by fee-for-service (FFS) Medicare patients. Several components of the evaluation are now either in press or in preparation. The evaluation of the process of routine and health maintenance care for ambulatory patients is presented here.

Methods

HMO Selection

There were several considerations in selecting the study's sample of HMOs. First, adequate representation of the four principal HMO models was a concern: staff HMOs, group HMOs, individual independent practice associations (IPAs), and network IPAs. Staff HMOs employ physicians and other providers directly; group HMOs contract one or more group practices. Individual IPAs contract with many individual physicians who care for HMO enrollees in their own offices; network IPAs contract not only with individuals but also with groups of physicians, with whom they usually share some of the risk for covered services. Because evidence suggests that IPAs function similarly to FFS practices, adequate representation of all four HMO models in the sample was important. Second, those plans with fewer than 2,000 Medicare enrollees were eliminated because they were unlikely to have enough cases for statistical power. Third, medical care often follows the conventional practices of the area, so adequate representation by geographic location was important. Finally, to secure the participation of HMOs and ensure confidence in the integrity of the study objectives, individual HMO plans were not identified in the analysis. From the pool of 27 HMOs in the demonstration, eight, distributed among the four major geographic areas, were selected for study. Four were staff or group model HMOs (staff/group) and four were IPA or network model HMOs (IPA).

Patient and Physician Selection

An important factor for selecting the sample of patients was that HMOs would have a high proportion of new evaluations. Routine care for new patients requires more

detailed medical record-keeping than is required for care of established patients. Therefore, the samples of both HMO and FFS Medicare patients were limited to those who had new patient evaluations during the study time frame, the period from each plan's enrollment date (range: January 1983-May 1984) to March 31, 1986. From the HMOs selected for study, an appropriate sample of patients was identified by age, Medicare status, and the name of the primary care physician. Those enrolled in the HMO before becoming eligible for Medicare were excluded, as were rollovers, patients who had seen the same physician under FFS.

For the FFS sample, primary care physicians with eligible patients were identified and recruited using master files from the American Medical Association and the American Osteopathic Association. Within the geographic areas used in selecting HMOS, 590 primary care physicians were identified. They were recruited in random number order by telephone, and their primary provider status confirmed. Screening eliminated 342 physicians, of whom 42 percent were ineligible because they could not be reached by phone, and the others for a variety of reasons: currently practicing in a staff/group model HMO, not in an office-based practice, no new patients during the study time frame, not in primary care, dead or retired. Of the 248 eligible physicians, 135 refused to participate and 113 participated in the study (recruitment rate, 46 percent). About 58 percent of the participating primary care physicians in the FFS sample reported also seeing HMO patients not enrolled in a staff/group model HMO.

Each participating physician was promised confidentiality for the information collected in the abstracting process. Stipends were offered; they were accepted by 13 percent of participating physicians. Almost 60 percent of the participating physicians were board certified in family practice or internal medicine. About 50 percent had graduated from medical school by 1970. These data were not available for individual physicians in the HMO sample because agreement to participate in the study was reached with the HMOs. However, physician lists from HMO plans overall indicated professional profiles similar to those in the FFS sample. To avoid over- or under-representing a particular style of practice in the sample, records for about 10 patients were abstracted for each physician in the two groups.

Abstraction Instrument Design

An advisory panel of physicians was assembled to develop detailed criteria lists for evaluating ambulatory care. The physicians were chosen on the basis of experience in quality of care research, background with prepaid medical plans, and recommendations from colleagues. Among them were both general internists and clinicians with expertise in geriatrics.

The panel developed three categories of ambulatory patient evaluation: medical history-taking, physical examination, and preventive screening. The first two represent time-honored bedside techniques, and as such were employed to measure the quality of care in new patient evaluations. Elements of preventive care, such as immunizations and screening procedures, were emphasized because substantial evidence supports their efficacy in health maintenance for the elderly.[6] The abstraction instrument used is available by request.

Medical Record Abstraction

Data were collected by 10 registered nurse abstractors who had been specially trained. They first completed a set of exercises mailed to them along with the training manual, and then attended five days of closely supervised sessions. For periodic health examinations abstractors were explicitly instructed to follow current guidelines.[6] When a recommended examination was not performed, statements were accepted for deferral or noncompliance (e.g., history of a hysterectomy).

Interrater reliability was assessed by having all 10 abstractors and the principal investigator (SMR) review a medical record. Agreement among raters was assessed by a variation of the kappa statistic.[7] Kappa values between raters ranged from .45 to .85, indicating good to excellent agreement among nurse abstractors for most items. The lower interrater values occurred with medical-history items, and the higher values with physical examinations, screening tests, and procedures.

Analysis

While the study focused mainly on new patient evaluations, the follow-up time for the analysis of screening tests and procedures was extended from the initial patient evaluation to the time of the chart abstraction. Because there were differences between groups, the duration of time after the patient's initial evaluation was considered a potential confounder. Others were age and gender, since many screening items are both age- and gender-specific. To control for these confounders, a logistic regression model was used to test the relationship between the patient's membership in an IPA model HMO, a staff/group HMO or a FFS system of care, and the performance of individual health maintenance procedures. Performance of each health maintenance item was used as a single binary (0–1) dependent variable. Age was entered into the model as a continuous variable. Group status, gender, and duration of follow-up time were entered as categorical variables (duration of follow-up: 0 = <20 months, 1 = ≥20 months). Maximum-likelihood estimates were computed, and 95% confidence intervals were constructed around each odds ratio.[8,9] Since the purpose of the demonstration was to determine if the care received by HMO patients was at least equal to the care received by Medicare FFS patients, odds ratios were determined by comparing performance in each HMO group of patients to the performance in FFS patients.

Results

Records of 1,590 ambulatory patients were abstracted; of these, 777 were FFS and 813 were HMO patients. Of the 813 HMO enrollees, 441 (54 percent) were from staff/group HMOs and 372 (46 percent) were from IPAs. As shown in Table 1, the FFS and the two groups of HMO patients differed on several characteristics. Patients who had new patient evaluations from both types of HMOs had been in the practices longer than FFS patients. The staff/group HMO patients had more active health problems than either IPA or FFS patients; the FFS patients were most likely to have diastolic hypertension and obesity. All three groups had similar proportions of patients with diabetes mellitus; patients from IPA HMOs were somewhat more likely than the other two groups to have a history of a previous cardiovascular event. There were slight differences in race and living situations, with patients from both HMO groups more likely to be White and less likely to live alone; however, there were considerable missing data for these two variables.

When initial medical histories in the three groups were compared, as shown in Table 2, consistent differences were

TABLE 1—Patient Characteristics in the Three Plan Types

Characteristics	FFS n = 777 (%)	IPA n = 372 (%)	Staff/Group n = 441 (%)
Mean age at time of first visit to practice (SD)	73.6 (6.4)	73.0 (5.9)	72.6 (6.0)
Mean number of months between first and most recent visits to practice (SD)	17.5 (13.6)	22.2 (12.2)	22.6 (11.1)
Mean number of ongoing health problems (SD)	3.1 (2.0)	3.1 (2.0)	3.8 (2.8)
Number of female patients	496 (63.8)	195 (52.4)	243 (55.1)
Number of married patients	290 (51.2)	181 (57.3)	253 (61.7)
Number of patients with diastolic hypertension	434 (55.9)	208 (55.9)	300 (68.0)
Number of patients with diabetes mellitus	134 (17.3)	73 (19.6)	85 (19.3)
Number of patients with history of previous cardiovascular event	252 (32.4)	90 (24.2)	172 (39.0)

TABLE 2—Initial Patient Evaluation: Percentage of Records with Selected Medical History Elements, According to Plan Type

Historical Elements	FFS n = 777	IPA n = 372	Staff/Group n = 441
Record of past health problems or hospitalizations	84.0	87.4	89.1
Record of drug allergies	72.8	82.3	83.5
Listing of current medications	82.8	90.6	90.9
Explicit Review of systems:			
Cardiovascular	58.5	61.5	64.2
Gastrointestinal	52.1	56.9	59.5
Genitourinary	47.4	54.2	61.2
Mental status	38.5	40.2	51.7
Musculoskeletal	47.0	50.4	59.7
Neurologic	43.2	48.3	57.4
Respiratory	55.0	58.0	60.4
Record of history of tobacco	63.3	70.4	78.0
Record of history of alcohol	56.4	65.9	69.2
Record of social history	39.6	39.0	38.1
Record of functional status	55.3	49.0	68.3

found. IPA and staff/group HMO patients were more likely to have their drug allergies and current medications listed. Staff/group HMO patients were more likely than either IPA or FFS patients to have a review of explicit system histories recorded, to have histories taken for tobacco and alcohol use, and to have a history of functional status recorded. Although IPA HMO patients had a greater likelihood of having an alcohol history taken than did FFS patients, they were less likely to have functional status information on their medical records.

Differences were also found among the groups with respect to the initial examinations, as shown in Table 3. As with medical histories, the consistent trend was for the records to show that examinations were more complete for patients in the two HMO models, especially the staff/group model.

TABLE 3—Initial Patient Evaluation: Percentage of Examination Elements and Laboratory Tests Recorded According to Plan Organization Type

Elements and Tests	FFS n = 777	IPA n = 372	Staff/Group n = 441
Examination of lungs	75.7	82.8	88.9
Examination of abdomen	74.1	84.7	88.4
Cardiac examination	73.6	80.1	90.9
Male genitourinary examination*	50.4	55.4	65.7
Peripheral vascular examination	50.2	49.5	59.4
Mental status examination	53.0	50.0	61.7
Neurologic examination	48.3	49.5	70.3
Urinalysis	66.4	70.2	88.9
Hemoglobin	79.4	79.8	93.9
Blood urea nitrogen or serum creatinine	71.3	75.0	93.2
Electrocardiogram	74.3	70.2	85.0

*Only males used in denominator

In Table 4, performance of periodic health examinations is examined using logistic regression. The odds ratios with 95% CI comparing the two HMO groups to FFS patients, controlling for age, sex and duration of follow-up, are shown. Overall, HMO enrollees from both models were significantly more likely than FFS patients to have periodic health maintenance as part of new patient evaluations and follow-up; however, the enrollees in staff/group model HMOs were particularly likely to receive preventive care.

Discussion

The prospect of a continuing rise in the cost of health care for the elderly increases the likelihood of further initiatives to control it. Prepaid care has already been advocated as a promising means of reducing utilization. However, rationing Medicare recipients' health care by increasing the financial risk for the provider raises questions about the quality of care.[10,11] Our findings revealed that ambulatory HMO patients were likely to receive more of the routine evaluation and health maintenance procedures than were ambulatory FFS patients. Differences in performance of screening tests currently recommended for the elderly were particularly striking for enrollees in staff/group model HMOs.

The finding that patients in HMOs had higher performance rates of recommended health maintenance items than did FFS patients suggests that attention should be given to the effects of the structure of medical practice on quality of care. Several investigators have pointed out that physician

TABLE 4—Odds Ratios of Performance of Periodic Health Examinations Comparing Medicare Patients in HMOs and FFS with Logistic Regression Analysis*

Examination/Procedure	Staff HMO::FFS	IPA HMO::FFS
Visual Acuity	3.69 (2.83, 4.80)	1.47 (1.09, 1.97)
Tonometry	8.39 (5.41, 12.99)	1.92 (1.28, 2.87)
Breast Examination	2.00 (1.41, 2.82)	1.37 (.95, 1.99)
Mammography	2.67 (1.84, 3.88)	1.31 (.84, 2.04)
Pelvic Examination	5.26 (3.51, 7.89)	1.15 (.80, 1.66)

Influenza Immunization	1.03 (.76, 1.39)	.44 (.30, .66)

*95% confidence intervals in parentheses

characteristics may play an important role, particularly in how they interact. Studies have suggested that medical practices incorporating significant peer interaction, such as HMOs, are more effective in reducing utilization than are those in which physicians practice independently, as in FFS practices.[12] It may also be the case that models with greater peer interaction more effectively support professional standards of care in the face of incentives to reduce utilization.[13,14] That feature of HMOs has the greatest potential to influence quality of care. Improved ambulatory care for Medicare recipients under prepaid systems may also be a result of HMOs' closer scrutiny of quality of care. Specific federal guidelines require quality assurance programs in HMOs.

While the results from this study may have important implications for health policy for the elderly, several limitations are worth noting. First, the study design did not allow for randomization of Medicare recipients into HMOs. Therefore, plan and physician selections may not have produced a representative sample, making application of the study results to the population of Medicare recipients in all HMO or FFS settings problematic; for example, it is possible that the FFS patients selected came from practices with unusually poor performance rates for standard elements of routine care. Nevertheless, among the elements of care received more often by the HMO enrollees, those constituting preventive care were most notable. Moreover, the performance rates for many of the preventive procedures received by patients in the study's FFS sample are comparable to rates reported in other FFS settings. For example, performance rates for FFS patients in nationwide surveys of clinical breast examination[15] and mammography[16] are remarkably similar to the performance rates among FFS patients in this study. Second, the study used a medical record review to determine performance rates for recommended items of routine care. It thus should be categorized as a study of the process of care and record-keeping. However, studies of the reliability and validity of medical records have established that technical aspects of medical care, such as preventive interventions, are likely to reflect actual performance.[17,18] Furthermore, for elderly patients the medical record itself is an especially important component of care, since their complex medical needs often call for multiple providers.

Although our study revealed that patients in HMOs receive medical care at least as competent as those in FFS practices receive, our analysis did not include an evaluation of individual HMOs. Our design plan was limited to representative models of group, staff, and two types of IPA HMOs, and only eight plans were studied. In that respect, the results from the evaluation of the demonstrations in this study should be interpreted with caution when establishing policy about all plans. Projects are currently under way to continue monitoring prepaid systems of care under Medicare.

Subject selection for this study was restricted to those who had been evaluated as new patients during the study time frame. However, the study did include data on patient follow-up visits for those periodic health examinations recommended after initial evaluation (e.g., annual mammography for women 50 to 59 years old). Therefore, the criteria for judging quality of care covered routine initial patient evaluations and follow-up periodic health examinations. The conclusions from the study are limited to those particular areas. Evaluations of the management of ambulatory patients with chronic illnesses, the follow-up of unexpectedly abnormal results, and the quality of care of inpatients are available in other reports.

The result that HMO enrollees received better preventive care may be due in part to the relative lack of reimbursement to FFS patients for the cost of screening tests. Others have noted that whether a patient undertakes recommended mammography, for example, is directly related to whether or not she can afford it.[19] Previous research has shown that preventive health care utilization is higher among HMO enrollees than among non-enrollees.[20] However, aside from procedures affected by reimbursement, HMO patients in this study were also more likely than FFS patients to have other examinations specifically recommended for the routine care of the elderly. For example, HMO enrollees were more likely to have current medications listed, an item especially important for elderly patients,[21] and enrollees in staff/group models were more likely to have functional status assessments. Furthermore, intraocular pressure and visual acuity were screened much more often in HMO enrollees than in FFS patients.

Efforts to regulate Medicare health costs must undergo careful scrutiny mindful of elderly patients' extensive medical needs. In this study, the scope of the conclusions is limited in that the quasi-experimental design restricted the findings to new patient evaluations in a demonstration program. The data showed that the elderly enrolled in HMOs received ambulatory care at least equal to what patients in FFS settings received; however, further evaluations are needed to verify that conclusion.

ACKNOWLEDGMENTS

This research was supported by a contract, No. 500-83-0047, from the Health Care Financing Administration. The study was presented in part at the annual meeting of the American Geriatric Society, May 13, 1989, Boston, Massachusetts.

The authors acknowledge the guidance of many individuals who helped in the design, data collection, and analysis phases for the National Medicare Competition. Among these, particular gratitude is extended to Kathy Langwell, Louis Rossiter, Randall Brown, Judith Wooldridge, Rhoda Cohen, Shelly Nelson, Nancy Carlton, Elizabeth Bates, Tamara Faulknier, and James Hadley. The contributions of those physicians who served on the expert panel for development of the criteria set for ambulatory care are also recognized. Statistical review was provided by Vernon Chinchilli. Finally, the authors gratefully acknowledge the valuable assistance and support provided by Anne Brooks, Beverly DeShazo, and Dorothy Silvers.

$5 Million Available for Pediatric AIDS Grants

Approximately $5 million is available for competitive grants for three types of AIDS (acquired immunodeficiency syndrome) Projects, according to an announcement from the federal Health Resources and Services Administration (HRSA). Six to eight awards will be made for **Pediatric AIDS Health Care Demonstration Projects** intended to demonstrate or develop:

- effective ways to prevent infection; particularly through reduction of perinatal transmission;
- community-based family-centered coordinated services for infected infants, children, and youth;
- programs to reduce the spread of HIV (human immunodeficiency virus) infection to vulnerable populations of young people.

Up to three grants will be made for **Pediatric AIDS Comprehensive Centers** intended to:

- establish public-private consortia among institutions and service providers; and
- develop a service, training, and research capability to support the community service base.

Four to six grants will be awarded for **National Issues of High Priority in Pediatric AIDS**. These grants will address critical issues for people with AIDS and their families, especially in prevention, early detection, and service provision. One grant in this category will establish a National Resource Center in Pediatric AIDS to identify and deal with issues that prevent patients and families from receiving services.

Public and private entities, nonprofit and for-profit, are eligible to apply for the grants. The *application deadline is April 9*. These AIDS project grants were announced in the February 13 issue of *Federal Register*.

Application materials are available from: Grants Management Officer, Bureau of Maternal and Child Health and Resources Development, Suite 100A, 12300 Twinbrook Parkway, Rockville, MD 20852; (301) 443-1440.

AIDS Risk Behavior Patterns among Gay Men in Small Southern Cities

JEFFREY A. KELLY, PHD, JANET S. ST. LAWRENCE, PHD, TED L. BRASFIELD, RTT, L. YVONNE STEVENSON, MS, YOLANDA E. DIAZ, MSW, AND ALLAN C. HAUTH, MA

Abstract: Men entering gay bars in three small southern cities were administered questionnaires to assess AIDS (acquired immunodeficiency syndrome) risk knowledge, perceived norms concerning the social acceptability of AIDS risk precautions, and personal sexual behavior. Seventy-seven percent (N = 355) of male patrons completed the measures. While risk knowledge levels were high, respondents did not perceive strong norms favoring risk reduction precautions. Rates of risk behavior were considerably higher than those reported for gay men in large urban epicenters. (*Am J Public Health* 1990; 80:416–418.)

Introduction

A number of cohort studies provide evidence that gay men in large-city AIDS (acquired immunodeficiency syndrome) epicenters have substantially modified behavior patterns to reduce risk for HIV (human immunodeficiency virus) infection.[1–5] Recent studies suggest that fewer than 20 percent of gay men in New York City and under 10 percent of gay men in San Francisco have engaged in unprotected anal intercourse during the past 12 months.[6,7] As a result, the prevalence of HIV infection among these populations has essentially reached a plateau, although at very high saturation levels.[8,9]

Less is known about the risk behavior patterns of homosexual men in smaller cities where HIV infection prevalence is still relatively low. For AIDS primary prevention efforts to be successful in these areas, there must be a rapid shift in sexual behavior norms and practices comparable to those already achieved by most gay men in AIDS epicenters. Limited research to date suggests that has not occurred.[10–12] The current study examined AIDS risk knowledge, perceived sexual behavior norms, and risk behavior patterns in a sample of homosexual men in small cities with currently low prevalence of AIDS.

Methods

Over consecutive three-night periods in the spring of 1989, all males entering gay clubs in three southern cities (Monroe, LA; Hattiesburg, MS; and Biloxi, MS) completed written questionnaires. A mean of 77 percent (range 56 percent to 85 percent) of all men entering each bar completed the study measures individually and without personal identifiers (N = 355). The three cities have metropolitan populations of 50,000 to 56,600 persons and are located at least 60 miles from any larger population center. While data on the number of AIDS cases in these cities are not available, the annual AIDS incidence in the study states (8.8/100,000 population in Louisiana and 5.8/100,000 in Mississippi) is much lower than that of states which have original AIDS epicenters (36.9/100,000 in New York and 20.9/100,000 in California).[13] Two of the cities have one gay bar while the other has two clubs; all were surveyed.

Each questionnaire requested demographic information and included probe measures of AIDS risk behavior knowledge, perception of norms concerning the acceptability of taking risk reduction precautions, and self-reported sexual activities over the preceding two months. The AIDS risk behavior knowledge measure consisted of 23 true/false items which tap practical understanding of high-risk sexual practices and risk reduction steps.[10] Five Likert-scale items (from 1 = strongly agree to 5 = strongly disagree) assessed the respondent's perception of peer norms and social consequences of taking risk reduction steps (Table 1). Each respondent also reported the number of times and the number of different sexual partners over the past two months for the sexual activities listed in Table 2.

Results

Preliminary analyses revealed no significant differences in risk behavior rates, knowledge test, and social norm scores across the three cities so data from all cities were pooled. The mean age of respondents was 28.3 years (SD = 7.9), mean educational level was 14.6 years (SD = 2.7), and 91 percent of the sample was White.

On the knowledge test, subjects correctly answered an average of 20.8 (SD = 2.3) of 23 items indicating accurate understanding of risk behavior. However, the social norms measure reflected only mixed perception that friends behaved safely or that insistence on condom use and safer sex practices would be well-accepted by others. Table 1 presents the distribution of responses for each item. While 81 percent of respondents were neutral or disagreed with the statement that condom use implies a lack of trust in a sexual partner, only 31 percent agreed or strongly agreed that their friends always use condoms during intercourse, only 43 percent agreed that peers used condoms or engaged in non-insertive practices, and 54 percent believed friends talk about safer sex more than they practice it. Respondent's mean score on these questions was 16.0 (SD = 4.1) of a maximum possible score of 25.

Eighty-three percent of respondents reported sexual activity over the preceding two months; 52 percent reported one partner and 48 percent reported multiple sexual partners. As Table 2 shows, 25 percent of all respondents reported engaging in unprotected insertive, and 23 percent unprotected receptive, anal intercourse during the past two months. For the total sample, the mean frequencies of these behaviors were 1.41 and 1.04 occurrences respectively. However, for subjects who engaged in any unprotected anal intercourse, the mean frequencies were 5.55 and 4.59 respec-

TABLE 2—Risk Behavior Patterns Reported by Study Respondents

Behavior	Number and Percentage of Total Sample Reporting Behavior in Past Two Months	Mean Frequency for Entire Sample in Past Two Months	Mean Frequency for Respondents Who Report Any Occurrence of the Behavior in Past Two Months	Mean Number of Partners for Behavior in Past Two Months for Subjects Who Report Any Occurrence of the Behavior
Unprotected anal intercourse as insertive partner	88 (25)	1.35 (4.85)	5.55 (9.45)	1.11 (.56)
Unprotected anal intercourse as receptive partner	81 (23)	1.11 (4.06)	4.59 (7.08)	1.03 (.62)
Unprotected oral intercourse as insertive partner, fluid exchanged	123 (35)	1.59 (3.76)	5.46 (11.12)	1.58 (2.91)
Unprotected oral intercourse as receptive partner, fluid exchanged	102 (29)	1.85 (6.11)	6.67 (11.08)	2.19 (5.75)

N = 352

tively. A proportionate calculation revealed that condoms were used by the insertive partner in only 51 percent of all anal intercourse occasions. In addition, 35 percent of the sample reported unprotected insertive, and 29 percent in receptive, oral intercourse with fluid exchange over the same two-month period. Finally, a median split was performed to subdivide the sample into those with high and those with low total scores on the social norm measure. Respondents with high social norm scores engaged less often in insertive and receptive unprotected anal intercourse and in receptive oral sex (Table 3).

TABLE 3—Means and 95% Confidence Intervals Comparing Sexual Behavior Practices of Respondents Scoring Above and Below Median in Social Norm Total Score

Sexual Practice Variable	Perceived Social Norm Score Median Split: Respondents in Upper Median M (95% CI)	Respondents in Lower Median M (95% CI)
Unprotected Insertive Anal Intercourse	0.6 (0.2,0.9)	2.3 (1.2,3.4)
Unprotected Receptive Anal Intercourse	0.4 (0.1,0.7)	1.7 (0.9,2.5)
Unprotected Insertive Oral Intercourse, Fluid Exchanged	1.3 (0.6,2.0)	2.6 (1.2,4.0)
Unprotected Receptive Oral Intercourse, Fluid Exchanged	0.8 (0.3,1.4)	3.0 (1.7,2.7)

N = 352

Discussion

Rates of high-risk sexual behavior in these cities are much greater than those recently reported for gay men in most large AIDS epicenters. The percentage of respondents in this study reporting unprotected anal intercourse during just the past two months is two to three times higher than the percentage of San Francisco gay men who report engaging in this practice during the last 12 months.[7] Conclusions that homosexual men have already effectively made changes needed to reduce risk for new HIV infection based upon large-city cohorts may not generalize to smaller cities.

Factual knowledge about AIDS was high in this sample. However, we suspect that gay men in small cities encounter fewer social supports for making AIDS precautionary behavior changes, do not benefit from well-organized community social structures which permit efficient behavioral norm redefinition, and still perceive AIDS as a distant threat. These social norms have considerable impact on gay mens' sexual behavior.[14]

The cross-sectional method used in this study does not permit conclusions to be drawn concerning behavior changes which may have occurred from earlier time periods, the sample is limited to patrons of gay bars in several southern cities, and there is a wide range in behavior reported by these respondents. Nonetheless, intensified primary prevention interventions are necessary for the many gay men in communities outside the urban areas who remain at great risk for HIV infection.

NIH Consensus Development Conference on Colon/Rectum Cancer, April 16–18

Adjuvant Therapy for Patients with Colon and Rectum Cancer is the subject of an upcoming consensus development conference sponsored by the National Institutes of Health (NIH). The conference, scheduled for April 16–18, 1990, in Masur Auditorium of the NIH Clinical Center, is open to the public.

The purpose of the conference is to reach agreement on adjuvant therapy for patients with colon and rectum cancer, as well as directions for future research.

Large bowel adenocarcinoma is a major public health problem in the United States. More than 150,000 new cases of colon and rectum cancer will be diagnosed in 1990 and approximately 75 percent will have a primary surgical resection with the hope of complete tumor eradication. Despite this high resectability rate, nearly half of all colorectal cancer patients die of metastatic tumor.

The conference will bring together specialists in surgery, oncology, gastroenterology, pathology, statistics, and other relevant fields. On the first two days, experts will present current scientific thinking about the diagnosis, management, and prevention of adjuvant therapy for patients with colon and rectum cancer, and concerned voluntary organizations will be invited to make statements. On the third day, after considering the scientific evidence, the consensus panel will present its draft report and invite comments from the audience. Glenn D. Steele, Jr., MD, PhD, New England Deaconess Hospital, will chair the panel.

To register for the Consensus Development Conference on Adjuvant Therapy for Patients with Colon and Rectum Cancer, or to obtain further information, contact: Conference Registrar, Prospect Associates, Suite 500, 1801 Rockville Pike, Rockville, MD 20852; (301) 468-MEET. FAX: (301) 770-5164.

HIV-1 Counseling and Testing Sites, Minnesota: Analysis of Trends in Client Charactertistics

Richard N. Danila, PhD, MPH, James M. Shultz, MS, PhD, Michael T. Osterholm, PhD, MPH, Keith Henry, MD, Margaret L. Simpson, MD, and Kristine L. MacDonald, MD

Abstract: We report here a summary of the data obtained from two HIV-1 antibody counseling and testing sites in Minneapolis-St. Paul for the first 48 months of operation (24,911 persons tested). The HIV-1 antibody seroprevalence rate for all persons tested was 5 percent. The highest seroprevalence rates were in male homosexual/bisexual intravenous drug users (23 percent) and homosexual/bisexual men (13 percent). There was a significant decrease in the HIV-1 antibody seroprevalence rate among clients during the 48-month period from 14 percent in the first six months to 3 percent in the last six months. This decrease coincided with an increase in the number of low-risk female clients and low-risk heterosexual male clients, and a decrease in the number of homosexual/bisexual males participating in the programs. These findings suggest the need for development and implementation of other strategies to identify and reach persons at highest risk for HIV-1 infection. (*Am J Public Health* 1990; 80:419–422.)

Introduction

In July 1985, the Minnesota Department of Health (MDH) established human immunodeficiency virus (HIV-1) counseling and testing sites at the two major public health sexually transmitted disease clinics in the Twin Cities (Minneapolis, St. Paul) to allow persons at risk for HIV-1 infection to ascertain their HIV-1 antibody status.

To examine the potential role of these Minnesota programs in HIV-1 infection prevention efforts, data on client demographic and risk factor characteristics and HIV-1 antibody seroprevalence were analyzed for the first 48 months of operation (July 1985 to June 1989).

Methods

The two programs provide free services to all persons requesting them. Prospective program clients are scheduled for appointments by telephone. All clients are interviewed by trained nurses or clinicians according to protocols established by the US Public Health Service Centers for Disease Control[1] and the MDH (available upon request to authors). During pre-test and post-test sessions, staff assess client risks for HIV-1 infection, interpret HIV-1 antibody test results, and provide individualized risk reduction and disease prevention counseling. Self-reported demographic and risk factor data are recorded on standardized client information sheets.

Serum specimens are initially screened for HIV-1 antibody using enzyme immunoassay (EIA) test kits from Abbott Laboratories, Electronucleonics, or Genetic Systems. Specimens are considered reactive if the absorbance values are above the cutoff levels specified by the manufacturers' instructions. Initially reactive specimens are tested a second time; specimens that are repeatedly reactive are then tested using the Western blot technique.[2] Western blot testing utilizes HIV-1 antigen from Bio-tech Dupont, Rockville, Maryland, or Litton Bionetics, Charleston, South Carolina. Specimens are considered positive by Western blot assay if the following bands are detectable: p24 or p31 and either gp41 or gp120/gp160, with or without additional HIV-1 characteristic bands.[3] Specimens with other HIV-1 band patterns not meeting the criteria for a positive assay are considered to be indeterminate.

Data were analyzed for 24,911 clients who had HIV-1 antibody serology completed from July 1985 through June 1989. Male clients were categorized into one of five HIV-1 transmission categories: homosexual/bisexual, homosexual/bisexual intravenous drug user, heterosexual intravenous drug user, heterosexual sex partner of a person at high risk for HIV-1 infection, or other (immigrant from a high-risk country or no identified risk). Female clients were categorized into one of three HIV-1 transmission categories: intravenous drug user, sex partner of a person at high risk for HIV-1 infection, or other (immigrant from a high-risk country, female prostitute, or no identified risk). Data were analyzed using standard univariate methods and chi-square test for trend measures.[4]

Results

Between July 1, 1985 and June 30, 1989, 25,306 client visits were recorded; 24,911 clients (98 percent) were tested for HIV-1 antibody and 395 clients (2 percent) declined testing after the pre-test visit. An increase occurred in the number of clients tested per month over the first 36 months with a leveling over the last 12 months (Figure 1). The HIV-1 antibody seroprevalence rate for all clients tested was five percent (1,299 of 24,911).

First-time and Repeat-Test Clients

For tested clients, 18,288 (73 percent) were persons being tested for HIV-1 antibody for the first time (first-time clients) and 6,623 (27 percent) were clients who had been tested at least once before (repeat-test clients). The HIV-1 antibody seroprevalence rate for first-time clients (898 of 18,288; 5 percent) was lower than the rate for repeat-test clients (401 of 6,623; 6 percent). For the repeat-test clients, 2,672 (40 percent) had been tested previously at a health department site, 353 (5 percent) at a family planning clinic, 306 (5 percent) at a physician's office, 81 (1 percent) at a plasma center, 58 (1 percent) at a blood collection facility, and 3,153 (48 percent) at other unspecified sites. Of the 401 clients who were HIV-1 antibody positive on the repeat test: 175 (44 percent) had tested positive for HIV-1 antibody previously; nine (2 percent) had prior tests with indetermi-

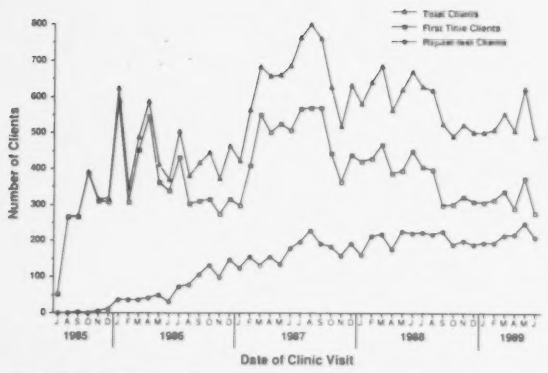

FIGURE 1—Number of Clients Attending Counseling and Test Site Programs Tested for HIV-1 Antibody by Visit. Status by Month, Minnesota, 1985-89

nate Western blot test results; 107 (27 percent) had previously tested either EIA negative or EIA reactive and Western blot negative; 33 (8 percent) had tested EIA reactive previously but had not had confirmatory Western blot testing performed; and information on previous testing was unavailable for 77 (19 percent).

Most clients (91 percent for first-time clients) were between 20 and 49 years of age. The HIV-1 antibody seroprevalence rate was higher in males than females (Table 1). The HIV-1 seroprevalence rate for Blacks was 1.6 times higher than the rate for Whites and the rate for Hispanic clients was 1.8 times as high as the rate for Whites.

The highest HIV-1 seroprevalence rate was found in male homosexual/bisexual intravenous drug users (23 percent; Table 2). Rates were also analyzed by transmission category and race for first-time clients; higher rates were consistently found in Black and Hispanic males (data available upon request to authors). HIV-1 seroprevalence rates for first-time clients were 6 percent and 4 percent at each of the two clinics, respectively; the higher seroprevalence rate was due to a larger proportion of homosexual/bisexual male clients seen at that site.

Total	6,128 (100.0)	22	0.4

Analyses of Trends Over Time

A significant downward trend in the monthly HIV-1 antibody seroprevalence rate was noted over time for all clients tested (both first-time and repeat-test clients) ($p < 0.001$) (Figure 2). The seroprevalence rate for all clients tested during the six months of testing in 1985 was 14.3 percent. The seroprevalence rate dropped to 8.3 percent during 1986 and declined further to 3.9 percent during 1987 and to 3.5 percent during 1988. During the first six months of 1989, the overall seroprevalence rate was only 2.5 percent.

The number and proportion of repeat-test clients increased significantly over time ($p < 0.001$) (Figure 1). Repeat-test clients accounted for 1.2 percent of all clients during the first six months of operation in 1985, but comprised 15.9 percent of all clients in 1986, 26.1 percent of all clients in 1987, 35.0 percent of all clients in 1988, and 40.2 percent of all clients during the first six months of 1989. This increase in the proportion of repeat-test clients did not account for the observed decline in the overall HIV-1 antibody seroprevalence, since the seroprevalence rate for repeat-test clients was actually higher than for first-time clients, as noted previously.

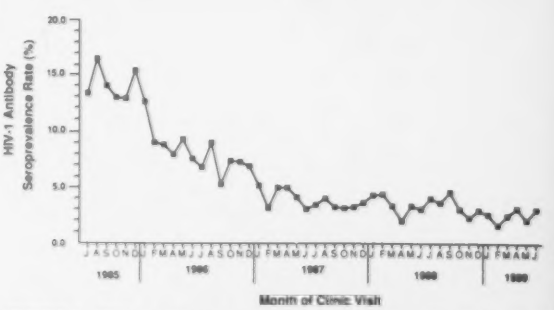

FIGURE 2—HIV-1 Antibody Seroprevalence Rates among Clients Attending Counseling and Test Site Programs by Month, Minnesota, 1985–89

Analysis of data from first-time clients only demonstrated that the HIV-1 seroprevalence declined from 14.2 percent for the first six months of operation in 1985 to 1.8 percent for the last six months of operation in 1989. The HIV-1 seroprevalence rate for repeat-test clients similarly declined from 26.3 percent in the first six months in 1985 to 3.5 percent in the last six months of operation in 1989 (data available on request to authors).

Major changes were noted in client characteristics over the 48-month period. Initially, most clients were at increased risk for HIV-1 infection; however, the number and proportion of clients at low risk for HIV-1 infection increased over time. During the first six months of the program, females comprised 8 percent of all first-time clients, whereas they made up 43 percent of all first-time clients during its last six months. During the first six months, 54 percent (69 of 128) of the females were at increased risk (intravenous drug user or sex partner of a person at high risk) and 46 percent (59 of 128) were at low risk; whereas, during the last six months, 33 percent (261 of 795) were at increased risk and 67 percent (534 of 795) were at low risk. There were no seropositive females in the first six months and only one for the last six months. During the first six months, 81 percent of all first-time clients were homosexual/bisexual males and 10 percent were heterosexual males; whereas, only 14 percent were homosexual/bisexual males and 43 percent were heterosexual males during the last six months of observation (Figure 3). For homosexual/bisexual male clients, a significant decline in HIV-1 antibody prevalence over time was noted ($p < 0.05$) (Figure 4).

Discussion

Counseling and testing site programs were originally conceived, funded, and opened in 1985 to assure safety of the blood supply by providing alternate sites for potential volunteer blood donors to ascertain their HIV-1 antibody status.[5] They have become a major cornerstone for AIDS (acquired immunodeficiency syndrome) prevention programs throughout the country and an integral part of the Minnesota statewide plan for AIDS prevention.[6] In evaluating the contribution of these programs to primary prevention of HIV-1 transmission, three issues need to be considered.

- First, are they currently serving clients most at risk for HIV-1 infection?
- Second, are they successful in HIV-1 infection prevention efforts through effecting and maintaining behavior change in clients?

- Third, are current counseling-testing program activities the best use of public health resources or are additional outreach strategies needed to target persons at highest risk of infection?

As these programs evolved in Minnesota over this 48-month observation period, they progressively served fewer clients at increased risk for HIV-1 infection and increasingly served clients at low risk for HIV-1 infection. A significant decrease in the number of homosexual/bisexual males seeking counseling and testing occurred over time. The HIV-1 antibody seroprevalence in homosexual/bisexual males seeking program services later in the observation period was lower than those seen early in the observation period, suggesting that men seen later were at lower risk for HIV-1 infection. In addition, 27 percent of the clients seen during this time period had been tested previously. Of these, most (97 percent) who initially tested negative were still negative for HIV-1 antibody on repeat testing. Some were clients who were instructed to return for follow-up testing to confirm their seronegative status, since they were in a potential "window-period" for HIV-1 antibody development based on their exposure history. Some of these repeat-test clients possibly were persons who continued to engage in high-risk behaviors. However, based on seroprevalence, it is likely that the majority of these repeat-test clients represent a low risk "worried well" population. Also, of the repeat-test clients who tested HIV-1 antibody positive, 175 (44 percent) had tested positive on a previous occasion, indicating that they likely were returning only to verify their infection status.

Counseling and testing site program policies remained stable during this time period. HIV-1 infection is a reportable condition in Minnesota and has been since shortly after the opening of these programs (October 1985), but clients are not denied services if they refuse to give a name or show proof of identity. This decrease in the number of persons at increased risk and corresponding increase in the number of persons at low risk for HIV-1 infection cannot be attributed to any change in program policy over the observation period. Also, similar trends demonstrating a decrease in HIV-1 seroprevalence at programs have been noted elsewhere in the country in states where HIV-1 infection is not reportable.[7–9]

Because long-term behavioral data were not collected at the sites, we have no direct measures of the effectiveness of our programs in promoting behavior change which prevents HIV-1 infection. Data on repeat-test clients can be used as an indirect measure. Of the 401 clients who were HIV-1 antibody positive on repeat testing, 107 (27 percent) had tested negative

previously; data are not available on the time of the previous test for 28 (26 percent) of the clients. Eighteen (17 percent) had tested HIV-1 antibody negative within the previous six months and thus may represent persons who were infected but had not yet seroconverted at the time of the prior test. However, 61 (57 percent) of the 107 clients reported testing HIV-1 antibody negative in the previous seven months or longer and thus may represent new infections due to ongoing high-risk activity, despite having received risk reduction counseling at the time of previous testing.

Current data regarding knowledge of HIV-1 infection status and subsequent behavior change are unclear and suggest different effects. Knowledge of HIV-1 infection, particularly of a positive status, has been associated with a reduction of high-risk behavior in some studies[10–17]; however, only one of these studies examined persons tested at counseling and testing sites. Other studies have not demonstrated behavior changes associated with knowledge of HIV-1 infection.[18–21] These studies may not necessarily be extrapolated to persons tested at counseling and testing sites nor are there data regarding long-term behavior change after a single instance of counseling and testing.

In recent years, large amounts of federal and state dollars have gone into expanding and maintaining HIV-1 counseling and testing sites. Approximately $1.4 million was spent in Minnesota on this program at these two sites during this 48-month observation period. Despite expenditure of these resources, the trends identified here indicate that the program may not be reaching persons at highest risk and that providing free services to anyone requesting them may not be the best use of available public health dollars for AIDS prevention. In areas such as Minnesota where heterosexuals (other than intravenous drug users) are at low risk for HIV-1 infection, services need to be targeted to those at highest risk. In addition, counseling and testing sites might attract more persons at increased risk for HIV-1 infection by being linked to additional services such as HIV-1 disease diagnostic and treatment services.

Strategies to both identify and develop outreach programs for those at highest risk are also needed. Clinic-based sites likely to provide services to persons who are engaging in high-risk behaviors, such as chemical dependency treatment programs and clinics for treatment of sexually transmitted diseases, need to have well-developed risk assessment programs and on-site availability of HIV-1 antibody testing. Other outreach strategies, such as programs involving street workers, need to be expanded. Third-party partner notification programs, which actively and selectively reach those at highest risk for HIV-1 infection, need to be considered by state health departments as another outreach mechanism.[22–24] The data presented here may not be applicable to all areas of the country, particularly where HIV-1 infection has become endemic in certain racial and high-risk groups. Criteria can be developed locally to determine which persons are at highest risk for HIV-1 infection and testing sites can then be tailored accordingly.

ACKNOWLEDGMENTS

The authors thank Mary Sheehan, MPH, Michael Moen, MPH, and Judy Beniak, MPH, for reviewing the manuscript. Robert Gillespie, MS, provided some data analyses. Counseling and testing activities were partially supported with funding from the Centers for Disease Control. Portions of this paper were presented at the V International Conference on AIDS, Montreal, June 4–9, 1989.

Potential for Laboratory Exposures to Biohazardous Agents Found in Blood

MICHELE R. EVANS, DRPH, DAVID K. HENDERSON, MD, AND JOHN E. BENNETT, MD

Abstract: The magnitude of risk for occupational exposures to biohazardous agents found in blood was assessed by 800 environmental samples taken from a total of 10 clinical and research laboratories at the National Institutes of Health (NIH). Thirty-one samples from 11 work stations in three laboratories contained hepatitis B virus surface antigen (HBsAg). Observations of workers indicated that environmental contamination arose from several sources. Among the 11 work stations with HBsAg environmental samples, eight had high work loads, seven had inappropriate behaviors, and nine had flawed laboratory techniques. This information suggests that a multifactorial approach is needed to minimize the risk of laboratory-associated infections. (*Am J Public Health* 1990;80:423–427.)

Introduction

Hepatitis B virus (HBV) infection is among the most commonly reported laboratory-associated infections.[1–4] Laboratory workers in an urban medical center are at almost three times the risk of acquiring HBV infection than other hospital employees, based solely on exposure to patients' blood.[5] HBV infection is seven to 10 times more common among occupational groups in laboratory medicine than in the general public.[6,7] Workers' anxiety is heightened because of the concomitant risk of acquiring other infections with human immunodeficiency virus (HIV) and agent(s) of non-A, non-B hepatitis.

Strict adherence to biosafety guidelines minimizes the risk of acquiring laboratory-associated infections.[8,9] Immunization of workers is clearly the most effective means to control infection.[10] However, many employees are reluctant to be immunized and, as is the case with HIV, licensed vaccines are not always available. Thus, these types of laboratory-associated infections continue to occur,[11] despite the fact that most are preventable. Recently, universal blood and body-fluid precautions were recommended to further enhance workers' safety.[12]

This study dealt with an assessment of similarities and differences in clinical and research laboratory activities concurrent with a survey to detect hepatitis B surface antigen (HBsAg) in the environment. For this study, HBsAg served as a marker for contamination with pathogens found in human blood. Based on data from viral survivability on fomites, the selection of HBsAg as a marker for blood-borne contamination exaggerates the viability of a labile microorganism such as HBV. Nevertheless, contamination with HBsAg suggests a common source and depicts a potential for transmission of infection in the laboratory. Given this caveat, the purpose of this study was to elucidate factors associated with HBsAg in the environment and, therefore, potential exposures to blood-borne pathogens in biomedical laboratories at the authors' institution.

Methods

Recruitment and Stratification of Laboratories

Ten laboratories, representing a cross section of operations involving the use of human blood at the National Institutes of Health (NIH), were entered into a survey conducted from August 1984 through February 1985. We invited 119 laboratory workers to participate. Each volunteer was assigned a code to assure anonymity.

The laboratories surveyed fulfilled criteria for assignment to Biosafety Level II[8] and were chosen to represent a spectrum from high to low risk of workers handling blood containing HBV. The 10 participating laboratories were divided into 44 distinct work stations for purposes of data collection. Each of these stations was assigned a level of risk prior to environmental sampling based on the volume of blood processed and the hypothesis that the probability of detection would be greater in laboratories which processed blood drawn from individuals known to be infected with HBV than from those which excluded such blood samples. High-risk work stations were arbitrarily defined as those locations where the estimated volume of blood processed per week equaled or exceeded 1.5 L or the specimens received were from individuals known to belong to groups with a high prevalence of HBV infection. Stations assigned to the low-risk category were arbitrarily defined as areas where workers processed less than 1.5 L blood per week, with all blood drawn from donors known to be negative for HBsAg.

There were 75 hours of direct observation with the amount of time per laboratory depending on the continuity of tasks involving the use of blood. Observations were obtrusive because this approach allowed for interviews with workers while laboratory activities were assessed.[13] Data obtained in this manner may have been biased because of the worker's apprehension and/or attempts to modify unsafe practices. To minimize worker's reaction to being observed, the investigator sought to establish a good rapport with participants, reiterate key issues of the study, and assure the worker's anonymity. Stratification of risk in the work stations of the laboratories surveyed and the observation periods completed are listed on Table 1.

Laboratories 2 and 3 (Clinical Pathology and Transfusion Medicine Departments, respectively) provided diagnostic services for the Warren G. Magnuson Clinical Center (the hospital at NIH); the majority of work stations in these two laboratories were classified in the high-risk category. The work completed in Laboratory 4 was classified in the high-risk category because numerous specimens were analyzed for large-scale serological surveillance studies. Individuals in

Laboratories 5, 7, 8, and 10 processed blood specimens that were obtained from patients with chronic liver disease or HIV infection. In Laboratory 9, a tumor immunology unit, workers analyzed specimens from patients likely to have a history of multiple blood transfusions.

Assessment of Laboratory Operations

Methods for assessing skilled performance (both behaviors and techniques) were adapted from a task strategies approach.[14] To control for spurious conclusions due to inconsistencies with data collection,[13,14] all data were recorded by a single investigator who reviewed the study parameters frequently to control for observer drift. No intervention was attempted during the study.

Observation of activities involving the use of human blood were assessed by two indices. First, the frequencies of 13 different manipulations were each tallied to estimate the extent of workers handling blood that was required in order to complete a task. A task was defined as the cumulative manipulations generating a single result. The second index was the work load (the number of blood specimens processed per week). These indices allowed for comparison of laboratories performing quite different operations.

Behaviors were also assessed in an attempt to identify practices associated with an increased risk of contamination. Specific behaviors were assessed when a worker performed a movement either accidentally or intentionally that involved contact between human blood and the employee's skin, conjunctiva, or mouth. Each behavior was classified either as appropriate, if the practice was consistent with biosafety recommendations,[8,9] or inappropriate, if the worker was placed at risk of an exposure (e.g., mouth pipetting fluids or skin contact with blood) as a result of a breach in good laboratory practices. In the event of an overt accident the worker's behavior was judged to be appropriate only if the contamination occurred despite good laboratory practices (e.g., mechanical failure or poor instrument design). Observations were tallied prior to knowledge of sample testing.

Environmental Survey

Samples collected for the detection of HBsAg were processed in a manner consistent with Biosafety Level II guidelines.[8] HBsAg was eluted from various surfaces using a modification of a procedure described by Favero, *et al.*[15,16] The elution fluid (FBS/PBS) was prepared using 20 percent fetal bovine serum (Lot #14-501B: M. A. Bioproducts, Walkersville, MD) (FBS), phosphate-buffered saline (0.15 M NaCl and phosphate: M. A. Bioproducts, Walkersville, MD) (pH 7.4 ± 0.5) (PBS), and sodium azide (1.0 mg/ml) (Sigma Chemical, St. Louis, MO).

Samples were collected from work surfaces measuring approximately 35 cm^2 using moistened swabs and from swatches of gloves worn by workers or absorbent paper placed on the work surface prior to handling blood. Pledgets (each with a surface area measuring 5.0 cm × 7.5 cm) cut from Grade 304 stainless steel by the Biomedical Engineering and Instrumentation Branch, NIH, Bethesda, MD, were used for indirect sampling. These pledgets were placed in the laboratories either in the working area or, for negative controls, outside the working space. Negative controls were graded unsatisfactory if the pledgets were either moved or visibly soiled during the exposure period. Metal pledgets were used because preliminary modeling studies demonstrated that nanogram amounts of HBsAg could be eluted from four surfaces (absorbent paper, glass, polystyrene, and stainless steel) with recovery rates averaging 20 percent, 77 percent, 82 percent, and 96 percent, respectively. Other data have shown that HBsAg can be recovered from metal surfaces with greater than 99 percent efficiency.[15] All samples were eluted in 1.5 ml FBS/PBS and stored at 4°C.

Hepatitis B Surface Antigen Detection

Samples were screened for the presence of HBsAg using a radioimmunoassay (Ausria II: Abbott Laboratories, Chicago, IL) according to the manufacturer's instructions with these modifications: a) each control and sample was assayed in duplicate using 200 ul eluate per well; b) six distinct negative environmental controls were assayed with each run; and c) each assay tube was counted for 10 min. Tubes were counted in a gamma spectrophotometer (Tracor Analytic, Model 1185: Nuclear-Chicago, Des Plains, IL) with a calculated counting efficiency for I-125 of 83 percent. The average cpm for each paired assay was calculated. Samples with discrepant paired results were retested. Those samples with repeatedly discrepant results were excluded from the study.

A sample was classified as reactive if the cpm for the sample was greater than three standard deviations from the mean cpm for the negative controls. The coefficient of variation (CV) was calculated and the mean of the negative controls for each screening run (values ranged from 3 percent to 17 percent with a mean of 7 percent).

Reactive samples were confirmed using specific neutralizing antibody for HBsAg (anti-HBsAg) (Ausria II Confirmatory Neutralizing Kit: Abbott Laboratories, Chicago, IL). Appendix A outlines the method used for the confirmation assay. A sample was confirmed HBsAg positive if the reduction in the cpm of the sample reacted with anti-HBsAg was greater than 50 percent compared with the sample reacted with FBS/PBS and if these latter cpm were between the range of 50 percent to 150 percent of the mean cpm of the negative control. Reactive samples with cpm less than 1.5 times the mean cpm of the negative control were diluted beyond the sensitivity of this latter assay and were interpreted as borderline. Within run variation for the confirmation runs was expressed as the CV calculated for the negative control (values ranged from 39 percent to 59 percent with a mean of 4 percent).

Statistics

The association of the potential factors with HBsAg was assessed by determining odds ratios and 95 percent confidence intervals.[17]

Results

The results for the HBsAg sampling data are summarized on Table 2. These data show that our hypothesis was correct: high-risk operations do differ from low-risk operations in terms of the potential for blood-borne contamination in the laboratory. All environmental samples collected from the low-risk work stations were negative for HBsAg. A total of 69 samples collected from high-risk work stations in Laboratories 2–4 and 8–10 were reactive for HBsAg on the initial screening. Except for the tumor immunology research unit, these laboratories routinely processed blood drawn from individuals chronically infected with blood-borne pathogens. Approximately 55 percent (38/69) of the reactive samples were graded as borderline (low cpm for positive samples overlapped with high cpm for negative controls). Insufficient eluate volumes prohibited further analysis of these borderline samples. Thus, we analyzed a total of 800 samples, of which 31 (3.9 percent) were HBsAg positive, 38 (4.8 percent) were borderline, and 731 (91.4 percent) were negative.

Samples confirmed positive for HBsAg were collected from Laboratories 2, 3, and 8. The HBsAg positivity from these laboratories ranged from a high of 17.8 percent (8/45) (liver disease research unit) to a low of 1.4 percent (2/139) (Transfusion Medicine). The frequency of obtaining positive samples in Clinical Pathology was 8.6 percent (21/245).

Factors Associated with HBsAg in High-Risk Work Stations

Individuals who worked in nine different locations in the Clinical Chemistry and Hematology Services had the highest work loads (average 1,430 specimens/week: range from 210–2,700). Workers in the Transfusion Medicine Department averaged 106 specimens per week. The liver disease unit, the laboratory with the greatest percent of samples positive for HBsAg, averaged 27 specimens per week. Work loads for Laboratories 4 and 7 averaged 1500 and 350, respectively. The remaining laboratories analyzed fewer than 60 specimens per week (range from 13–60).

Inappropriate behaviors associated with an obvious risk for cutaneous contact with blood were identified at nearly 40 percent (15/39) of the areas surveyed. One example of these inappropriate work practices which occurred was that workers routinely handled contaminated fomites without wearing gloves. Despite the presence of warning labels (e.g., blood and body-fluid precautions) on some specimens, workers at 60 percent (9/15) of these same areas were not motivated to wear gloves. Workers who consistently wore gloves when working with blood (whether a warning label was present or absent) were observed at only 33 percent (13/39) of the stations. Surprisingly, two workers who routinely analyzed blood donned gloves only when they handled blood with a warning label.

Four workers committed flagrant violations of good work practices during the observations. These individuals either mouth-pipetted serum or live virus suspension or splashed milliliter amounts of body-fluid onto their skin. They were also observed to disregard basic hygienic practices (e.g., placing laboratory marking pens in the mouth) and misused equipment. Examples of other unsafe work practices observed in this study included: sonicating infectious materials without physical containment and hand braking a centrifuge rotor. Curiously, three employees acknowledged that they were aware of the risks associated with their actions.

Table 3 shows the frequencies and crude odds ratios of HBsAg contamination in 39 high-risk work stations. High work load and flawed technique were associated with the greatest risk of contamination, whereas there was a borderline association with inappropriate behavior (Table 3). Flawed techniques were of two kinds: those related to instrument design and those related to procedures which were intrinsically defective (i.e., workers may have been following the procedure as described, yet blood spills routinely occurred).

Approximately 85 instruments that workers used during the study were sampled for HBsAg. The design of these instruments was considered flawed if a mechanical feature generated a spatter of blood or necessitated frequent maintenance of components contaminated with body-fluids. HBsAg was detected on surfaces near several instruments where blood was spattered: Sequential Multiple Analyzer and Computer, Model SMAC II Systems: Technicon Instruments Corporation, Tarrytown, NY; Automated pH/Blood Gas System, Model 175: Corning Medical and Scientific, Medfield, MA: Pentawash II: Abbott Laboratories, Chicago, IL; and Coulter Counter, Model S-Plus System, Coulter Electronics, Inc., Hialeah, FL. Similarly, HBsAg was detected on instruments designed with samplers that required external washing. Compared with all other types of instruments surveyed in our laboratories, the continuous flow analyzers were the most vulnerable to malfunctions of

<30	10/29	
≥30	1/10	0.21 (0.04, 1.92)

intricate serum-containing components. All of these design features were associated with an increased occurrence of contamination in our laboratories.

Instruments with discrete reaction containers and samplers with fluid sensors that do not require external wash steps minimize contamination. Visible soiling was not observed and HBsAg surveys were negative after operating the following instruments: Automatic Clinical Analyzer III: Dupont Instruments, Wilmington, DE; Automated STAT/Routine Analyzer-8: Beckman Instruments, Brea, CA: Immunochemistry Systems Analyzer II: Beckman Instruments, Brea, CA; and Cobas-BIO: Roche Analytic Instruments, Inc., Nutley, NJ.

Techniques which frequently resulted in blood spills, despite observations that workers adhered to written procedures, were considered defective because these methods did not reasonably ensure containment of biohazardous fluids. They were frequently associated with a need for repetitious separations and intermittent mixing of blood without adequate measures to contain spills. Both image and flow cytometric systems were identified as techniques with the most frequent occurrence of overt spills. These types of systems were associated with the presence of HBsAg in Laboratories 2, 3, and 8.

To approximate the risk of contamination when processing blood contained in vacuum-sealed tubes, samples were collected from a device designed for removing rubber stoppers from tubes. Operation of the device entails aligning the tube into an opening and, then, mechanically directing a metal arm to swing against the stopper forcing it to pop off simulating the manual technique. HBsAg was detected repeatedly on the rim of the device opening where spatter occurred. These data suggest that removing stoppers by either method is a subtle source of contamination. We endorse the technique of "wrap and snap" to minimize spatter of blood.

Tasks with few manipulations usually involved processing small volumes of blood using microscale techniques (both manual and automated). Automated instruments were used in 8 of 15 stations surveyed in Clinical Pathology compared with only 2 of 11 stations in Transfusion Medicine. Exclusive of the flow cytometry service, only manual techniques (e.g., immune profiles) were observed in the remaining research laboratories. Automated assays using less than 15 ml of blood averaged three manipulations per task: whereas, comparable manual assays averaged 10 manipulations per task. Tasks using greater than 1 L of blood required the most handling (average 30 manipulations/task: range from 6–92). These latter procedures were typically performed in research laboratories.

To examine the association between different tasks and contamination, we arbitrarily grouped each work station into those involving less than 30 manipulations and another group with 30 and more activities (complex tasks). In contrast to the factors mentioned earlier, complexity appeared to be inversely associated with contamination (OR = 0.21, 95% CI = 0.04, 1.92) (Table 3). A review of the data revealed that complexity was inversely correlated with work load (no complex tasks were performed in stations with high work load).

To further examine the predictors of blood-borne contamination, logistic regression analysis was performed to determine the effects of the factors shown on Table 3 while controlling for the effects of each other. Because of the negative correlation between complexity and high work load, we chose to remove complexity from further analysis. In the analysis with the three remaining factors, the point estimates for the adjusted odds ratio for flawed technique decreased to 9.78 (95 percent CI = 1.46, 65.49) and was the factor most strongly associated with HBsAg. Only a modest decrease in the adjusted odds ratios was observed for high work load (OR = 5.06, 95% CI = 0.80, 31.96) and inappropriate behavior (OR = 2.75, 95% CI = 0.44, 17.4) compared with the crude odds ratios. In a similar analysis with only two variables, both high work load (OR = 6.82, 95 percent CI = 1.73, 39.66) and flawed technique (OR = 9.78, 95 percent CI = 1.52, 63.01) were associated with an increased risk of blood-borne contamination. (Data available on request to authors.)

Discussion

Data from our study are consistent with the concept that workers who process blood from numerous donors (high work loads typically associated with diagnostic testing) increase their risk of occupational exposures to blood-borne pathogens. However, a high prevalence of HBV infection among blood donors can also contribute to risk. For example, the liver disease research unit had the highest HBsAg positivity rate (17.8 percent) but only averaged 27 specimens/week. One-third of the specimens submitted to this laboratory were from individuals known to be chronic carriers of HBV, compared with the other laboratories surveyed where fewer than one-tenth of the specimens were obtained from infected patients. It is important to note, however, that an analogous risk can be identified in any laboratory where serial specimens from infected patients are analyzed (e.g., therapeutic drug monitoring, diagnostic microbiology, and similar types of research involving HBV or HIV). In support of this observation is the recommendation that the function or nature of the laboratory should also be considered in the hazard assessment to protect these workers.[8]

Inappropriate behaviors (a second factor associated with HBsAg) were noted when workers disregarded standard practices or misused equipment. Somewhat alarming were observations that individuals at almost 50 percent of the high-risk areas experienced a seemingly innocuous, but preventable cutaneous contact with blood as a result of poor work practices. Complacency regarding the wearing of gloves while handling contaminated fomites was cited as the most frequent cause of these exposures.

During 75 hours of observation, only four overt accidents resulting in contact between the employees' protective garb and blood were observed. No accidental parenteral inoculations occurred and none of the four accidents was associated with inappropriate behaviors. These data can be contrasted with our observations cited above that poor work practices were associated with the employee experiencing cutaneous contact with blood. Based on these data, we concluded that the majority of exposures to blood that occur in the laboratory are occult in nature, as well as, preventable. Further, the risk of processing blood containing a pathogen is likely to be underestimated.[18] Despite the presence of warning labels on specimens submitted to NIH laboratories, during our observations, the majority of workers who engaged in poor work practices were not motivated by these labels to modify their inappropriate behaviors. Equally important was our observation that none of the individuals with good work practices experienced an adverse exposure to blood. In combination, these data reinforce the concept that workers who handle human blood strictly adhere to precau-

tions as an effective means to reduce their risk of laboratory-associated infection. These practices were observed prior to the implementation of universal precautions in our hospital.[12]

Our results indicate that automation contributed to contamination only when the design of certain instrument components was flawed with respect to containment.[19] Just as good engineering design can be negated by poor work practices, flawed design (the factor associated with the greatest risk of contamination) can also overcome good work practices.[9] Our study demonstrates the need to modify instrument components which represent an increased risk for contamination and, perhaps, infection among laboratory workers.

Manual techniques such as cytometric systems that involved sequential manipulations of specimens represented an increased risk for contamination in our laboratories. The frequent presence of HBsAg in these areas indicates that blood-borne contamination is predictable for many of these procedures. We concur that workers should modify these techniques in order to enhance their safety.[9]

In our study, the complexity of laboratory tasks (in terms of cumulative manipulations per task) was weakly associated with the risk for HBsAg. Also, we observed a negative correlation between complexity and high work load which probably reflected differences in the processing of specimens for research protocols compared to diagnostic testing. We submit, therefore, that the complexity of tasks performed represents minimal risk to the worker and recommend that predictors associated with greater risk of blood-borne contamination be given priority in the assessment of laboratory safety. Use of these data and previously published data[2,8,12] in designing interventions to eliminate adverse exposures to blood may prevent implementing strategies that unnecessarily disrupt the laboratory while not enhancing worker safety.

APPENDIX A

Method Used for HBsAg Confirmation Assay

Modifications to the manufacturer's instructions (Ausria II Confirmatory Neutralizing Kit: Abbott Laboratories, Chicago, IL) were as follows. The HBsAg positive control (Ausria II: Abbott Laboratories, Chicago, IL) was processed in the same manner as the samples. After the addition of a polystyrene bead coated with guinea pig anti-HBsAg, 150 µl of eluate or HBsAg positive control were dispensed to each of four wells. The negative control (FBS/PBS) was assayed in replicates of six using 150 µl per well. After the initial wash step, 150 µl of FBS/PBS (diluted 1:5 with 0.9% NaCl) were added to the negative control wells. Each tray was incubated (25°C for 16–24 h). Each well was then washed four times using 5 ml distilled water per rinse. A 150 µl volume of confirmatory anti-HBsAg (diluted 1:5 with 0.9% NaCl) were added to two of the four wells and 150 µl of FBS/PBS (diluted 1:5 with 0.9% NaCl) were added to the remaining two wells of each set of assays and to each of the negative control wells. Each tray was incubated (45°C for 1 h). Without aspirating the contents of the well, 200 µl of I-125 anti-HBsAg were then added to all of the wells and allowed to react (45°C for 1 h). After repeating the wash step, each bead was counted.

The average cpm was calculated for each replicate assay that reacted with either anti-HBsAg or FBS/PBS. The percent reduction in the cpm for the positive control and each sample was calculated using the following formula:

$$\% \text{ Reduction} = \frac{\{\text{cpm(sample + FBS/PBS)} - \text{cpm(sample + anti-HBsAg)}\} \times 100}{\{\text{cpm(sample + FBS/PBS)} - \text{cpm(negative control)}\}}$$

Validity of a confirmation run was based on two arbitrary criteria: 1) neutralization with anti-HBsAg had to result in a greater than 50 percent reduction in the cpm for the positive control when compared to the cpm of the control reacted with I-125 anti-HBsAg (the parameter was >97 percent for each run); and 2) no more than two replicates of the negative control could be considered aberrant. This latter event did not occur. However a single value was greater than 1.5 times the mean of the negative control for three of the five runs. In each case, the aberrant value was excluded and the mean recalculated.

ACKNOWLEDGMENTS

We thank Drs. Stanley Lemon of the University of North Carolina and Gary Coslett of Abbott Laboratories for providing some of the reagents and equipment. We also thank Ms. Deloris Koziol and Dr. Steven Banks for their assistance in analyzing the data. We especially thank the NIH laboratory directors and staff whose participation made this study possible. This work was supported in part by the Division of Safety at the NIH and fulfilled partial requirements for a doctoral candidacy from the School of Public Health at the University of North Carolina. An earlier version of this paper was presented at the 28th Biological Safety Conference in La Jolla, California on October 21, 1985.

Recovery of Hepatitis A Virus from a Water Supply Responsible for a Common Source Outbreak of Hepatitis A

Alan B. Bloch, MD, MPH, Susan L. Stramer, PhD, J. David Smith, BS, Harold S. Margolis, MD, Howard A. Fields, PhD, Thomas W. McKinley, MPH, Charles P. Gerba, PhD, James E. Maynard, MD, PhD, and R. Keith Sikes, DVM, MPH

Abstract: An outbreak of hepatitis A occurred in a north Georgia trailer park served by a private well. Of 18 residents who were serosusceptible to hepatitis A virus (HAV), 16 (89%) developed hepatitis A. Well water samples were collected 3 months after illness onset in the index case and 28 days after illness onset in the last trailer park resident. Hepatitis A virus antigen (HAVAg) was detected in the samples by enzyme immunoassay from three of the five cell lines following two 30-day passages and from a fourth cell line following a third passage of 21 days. (*Am J Public Health* 1990; 80:428–430.)

Introduction

Infection with hepatitis A virus (HAV) accounted for 39 percent of the 59,633 cases of acute viral hepatitis reported in the United States in 1985.[1] Virus transmission occurs primarily through the fecal-oral route, resulting in both sporadic cases and common source outbreaks.[2] Common source outbreaks of hepatitis A have been associated with ingestion of contaminated food[3,4] or consumption of inadequately treated drinking water.[5–9] The incrimination of food and water in HAV transmission has largely been based on the epidemiologic characteristics of the outbreak and serologic evidence that the resulting viral hepatitis was type A. Only recently has HAV been recovered from water associated with hepatitis A outbreaks.[10]

HAV is classified as a picornavirus, and most wild-type HAV does not produce a cytopathic effect, although infectious units can be quantitated by the radioimmunofocus assay (RIFA).[11] We describe the cell culture isolation of HAV from drinking water implicated as the source of virus transmission in a common source outbreak.

Methods

Epidemiologic Investigation

A 21-year-old man had onset of serologically confirmed hepatitis A on July 10, 1982 while living from July 9 through July 23 in a trailer park in Bartow County, Georgia. Approximately three to nine weeks following onset of illness, other residents of the trailer park developed hepatitis A. All cases of hepatitis A during 1982 were identified using county health department case reports and laboratory records for hepatitis A serologic testing. Each trailer park resident was interviewed and a blood sample obtained. All serum samples were tested by radioimmunoassay for total and IgM-specific antibody to HAV (HAVAB and HAVAB-M, Abbott Laboratories,* North Chicago, IL).

Case Definition

A case was defined by a positive serologic test for IgM anti-HAV. One trailer park resident who declined a blood test but reported a history of jaundice and abdominal pain was also included.

Water Sampling

Tap water from the trailers was tested for fecal coliform bacteria by standard methods.[12] Fluorescein dye was discharged from the toilet of the index case, and tap water samples were collected after 19 and 81 days.

Three months after onset of illness in the index case, 400 and 1600 liters of ground water from the well pump supplying the park were passed through an electropositive charge-modified, 25-cm long, cellulose-diatomaceous earth composite, microporous filter (Virosorb 1MDS; Cuno, Meriden, CT).

Cell Cultures

Adsorbed viruses were eluted from the filter cartridges with 1 liter of 3 percent beef extract adjusted to pH 10, and after elution, sufficient 1M glycine was added to lower the pH to 3.5. The flocculated organic material was processed according to the method of Katzenelson, *et al.*[13] Virus culture was carried out in four monkey kidney cell lines: BGM, BS-C-1, FRhK-4 (American Type Culture Collection, Rockville, MD) and MA104 (Microbiological Associates, Bethesda, MD); and in primary Rhesus monkey kidney (PMK) cells.

The concentrated sample was filter sterilized directly onto the cell monolayer, and virus was adsorbed at 37°C for two hours with periodic rocking. PBS mock-infected cell cultures were included for controls. All cells except FRhK-4 were grown in Eagle's minimum essential medium containing Earle's balanced salts solution and supplemented with 10 percent fetal bovine serum, 25 mM HEPES (N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid), 2 mM L-glutamine, 0.1 mM nonessential amino acids, 0.2 percent sodium bicarbonate, and antibiotics (20 mcg/ml gentamycin, 100 mcg/ml streptomycin, and 100 U/ml penicillin). FRhK-4 cells were grown in William's medium E as previously described.[14] Maintenance media consisted of the same basal medium

containing 2% fetal bovine serum. All media and media components were obtained from Gibco Laboratories (Grand Island, NY).

Continuous cell lines were passaged twice at 30-day intervals and four times at 21-day intervals. Virus was recovered from PMK cells by trypsinizing, freeze-thawing, sonication, extraction with 2,3,5 trichloro-trifluoroethane (Dupont Chemicals, Wilmington, DE), and passaged acutely.

Assays for HAV

Trypsinized cell samples were extracted as described above and assayed for HAVAg with a double-antibody sandwich enzyme immunoassay (EIA), as previously described.[15] A ratio of positive to negative values (P/N) >2.1 was considered positive for HAVAg.

Infectious units of HAV were quantitated by the RIFA, using both human and rabbit anti-HAV.[11] HAV titers were expressed as radioimmunofocus-units (RFU) per ml.

Results

Epidemiologic Investigation

Thirty-five cases of hepatitis A with onset of illness from July 10 to November 24, 1982 were identified in the county. Before July 10, there had been no reported hepatitis A cases in the county during 1982. Of the 35 cases, 17 were residents of the trailer park. In 31 cases the date of onset of symptoms could be recalled (Figure 1). Among the 13 residents of the trailer park who could recall date of onset of illness, 12 became ill within 22 to 41 days following disease onset in the index case.

The index case was a 21-year-old male who lived with a family in the trailer park from July 9 to July 23. He denied contact with the seven other families in the park. Of the 30 trailer park residents, seven had serologic evidence of prior exposure to hepatitis A. The five persons living with the index case received immunoglobulin prophylaxis, and one became IgM anti-HAV positive. Among the 18 remaining trailer park residents considered serosusceptible to hepatitis A, 16 developed hepatitis A (89 percent attack rate). The epidemiologic investigation revealed no common social activity, meal, or food which could account for the outbreak. The only two serosusceptible individuals who did not become ill were 11 and 18 months of age, and their mothers were positive for total anti-HAV but negative for IgM anti-HAV.

Of the 18 cases who were not residents of the trailer park (including the index case), 11 had visited the trailer park and drunk water during their visit (Figure 1). Another four patients had contact with cases only outside the trailer park, while three had no known contact with other cases.

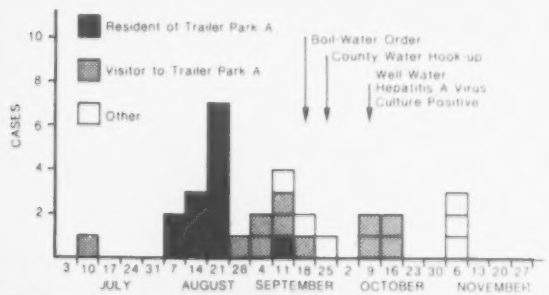

FIGURE 1—Onset of Reported Hepatitis A Cases with Known Date of Onset in Bartow County, Georgia, July through November 1982. (A county order to boil water was issued September 17. The trailer park was connected to the county drinking water supply on September 24. The hepatitis A virus-containing water samples were collected from the implicated well on October 6.)

Environmental Investigation

The trailer park's sole water supply was a 15-cm diameter drilled well having a depth of 24 to 30 m, encased within steel pipe. The trailers encircled the well at a distance of 18 to 60 m, and water was distributed through a 2-cm galvanized pipe buried approximately 50 cm below the ground surface. Wastewater from each trailer was treated by individual septic tank systems having gravity feed, subsurface drainage tile distribution networks; each septic tank system was separated from the well by a distance of 30 to 60 m.

The concentration of fecal coliforms in tap water ranged from zero to greater than 16 per 100 ml and in water collected from the wellhead was 2 per 100 ml. Fluorescein dye was flushed from the toilet of the trailer in which the index case had lived, but could not be detected on days 19 and 81 after charging the system.

A boil-water order was issued on September 17, and on September 24 the well was disconnected, and the water distribution system was connected to the county water supply.

Virus Assays

HAVAg could not be detected in the ground water concentrates by EIA. Following amplification in cell culture, HAVAg was detected in the monkey kidney cell lines (Table 1). After primary cell adaptation to FRhK-4 and PMK cells, foci of HAV were detected by RIFA (Figure 2). Passage in FRhK-4 and PMK cells yielded titers of 3.0×10^7 RFU/ml and 2.0×10^7 RFU/ml, respectively.

Discussion

The importance of HAV transmission by water is probably underestimated since outbreaks appear to be infrequently reported, poorly documented, and the virus has been only rarely isolated from this source.[9,10,16] Using currently available methods for enterovirus detection, HAV can be concentrated 100- to 10,000-fold onto microporous filters and concentrated another 10- to 100-fold by organic flocculation.[10,16,17] In one study in which these concentration techniques were used, samples of ground water implicated in a large outbreak of hepatitis A revealed low levels of HAVAg by RIA.[16] In contrast to a previously reported outbreak where HAV was isolated from contaminated water,[10] the fecal coliform counts obtained at the peak of the presumed period of contamination in the present outbreak were 10- to 100-fold lower, suggesting

that low levels of ground water contamination can produce significant outbreaks of hepatitis A.

This outbreak also demonstrated the stability of HAV in untreated water. The water samples from which the virus was isolated were obtained three months after the onset of symptoms in the index case and 28 days after the onset of symptoms in the last trailer park resident (Figure 1). The recovery of HAV suggests that the contaminating virus had continued access and persisted in the aquifer supplying the well although it cannot be ruled out that fourth generation cases (illness onsets from October 4 to 13) who were visitors to the trailer park, may have recontaminated the aquifer. In addition, the water concentrates were stored at 4°C for eight months before they were inoculated into cell culture.

While the incidence of HAV infection has been decreasing in the US over the past 10 years, it continues to be the second leading cause of viral hepatitis. Although the majority of the population utilizes municipal drinking water, it is evident that well water contamination with HAV continues to occur and that this source of infection is not widely appreciated.

Review Criteria for Schools of Public Health Funding, Project Grants

Final review criteria, funding priority, and special consideration for special project grants to Schools of Public Health were published in the February 8 issue of the *Federal Register*. Among the review criteria to be considered is whether the project contains realistic objectives as described in *The Future of Public Health, Objectives for the Nation* and the *Sixth Report to the President and Congress on the Status of Health Personnel in the United States*.

The funding priority is designed to promote health initiatives that will encourage and increase involvement of underrepresented minority health trainees. Special consideration will be given to applications that address five issues:

- Substance Abuse
- HIV/AIDS
- Geriatrics
- Environmental health
- Training students to work in public health agencies

A Rural Outbreak of Legionnaires' Disease Linked to Visiting a Retail Store

Stephen C. Redd, MD, Fen Yeng C. Lin, MD, MPH, Barry S. Fields, PhD, Jeanne Biscoe, RN, Bonnie B. Plikaytis, MS, Patricia Powers, RN, Jagdish Patel, PhD, Boon P. Lim, MD, MPH, J. Mehson Joseph, PhD, Chinnadurai Devadason, MD, DrPH, Ebenezer Israel, MD, MPH, and Mitchell L. Cohen, MD

Abstract: Between May 7 and June 7, 1986, 27 residents of a rural county in Maryland developed legionellosis, and two died. *Legionella pneumophila* serogroup 1 was cultured from the sputum of two patients and identified in lung tissue of a third patient by direct fluorescent antibody staining. An additional 11 patients had four-fold rises in antibody titer to *L. pneumophila*, and 13 had single titers ≥1:256. To determine risk factors for disease, we performed a case-control study. Twelve of 16 case-patients reported visiting store A in the two weeks before onset of illness compared with four of 28 control-patients. A serologic survey of employees showed that employees of store A were 3.63 times more likely than control employees to have titers of antibody to *L. pneumophila* ≥1:256 (95% confidence intervals 0.8, 16.7). Cultures of soil specimens, samples of water from the hot water system of store A and from stagnant ponds near store A collected five weeks after the end of the outbreak were negative for *Legionella* species. Store A was adjacent to a site of excavation and construction during May 1986, when the community was experiencing an extended drought. This investigation suggests that exposure to excavation and construction activity may be a risk factor for legionellosis. (*Am J Public Health* 1990; 80:431–434.)

Introduction

Investigators agree that *Legionella pneumophila* is ubiquitous in nature, but they disagree about the importance of various modes of transmission.[1] Attention has focused on inhalation of organisms from water droplets in aerosols and aspiration of contaminated potable water as predominant modes of transmission. These conventional assumptions of how legionellae are transmitted are inadequate to explain outbreaks associated with construction and excavation when aerosols or potable water sources are not implicated. In this report we describe a community outbreak of legionellosis that was not associated with an aerosol or contaminated potable water. Exposures to excavation and construction were the only identifiable risk factors.

During the third week of May 1986, the staff radiologist of a community-hospital in a rural county of Maryland recognized an unusual cluster of cases of severe community-acquired pneumonia. The Maryland State Health Department and local county health department were notified and an investigation was initiated. Review of chest radiograph reports confirmed an increase in the number of both hospitalized patients and outpatients with radiographic evidence of pneumonia in May 1986 compared with April 1986, April 1985, and May 1985. Cases identified by this review had a wide range of clinical findings, and initial microbiologic studies did not implicate any single pathogen.

Methods

We defined cases of outbreak-associated Legionnaires' disease as follows: onset of symptoms consistent with pneumonia during May 1986, residence in county A, and either isolation of *L. pneumophila* serogroup 1 from a clinical specimen, fluorescent antibody staining of organisms from tissue, four-fold rise in antibody titer to *L. pneumophila* serogroup 1 to a titer ≥128, or a single antibody titer ≥256.

Cases were ascertained by reviewing all reports of chest radiographs performed on inpatients and outpatients during May and June 1986 at the only hospital in the county, clinical histories recorded in charts of patients reported to have pneumonia, and the reports by community physicians of patients with pneumonia. Convalescent-phase serum specimens were obtained on 52 suspect outbreak patients with pneumonia; for 41 patients an acute-phase serum specimen was also obtained.

Isolates of *L. pneumophila* obtained from patients were subtyped by the pattern of binding of a panel of monoclonal antibodies to *L. pneumophila*.[2]

To determine risk factors associated with illness, we performed a case-control study. Since laboratory data were unavailable at the time the case-control study was performed, we used a clinical case definition—temperature ≥101°F, white blood cell count ≥11,000 cells/mm^3, and dense pulmonary infiltrate by chest radiograph. A questionnaire was administered to each case-patient by phoned interview that lasted approximately 10 minutes. We asked whether the patient had visited any of eight specific locations in county A in the two weeks before illness onset and if so, on what date and at what time; whether the patient would have visited these locations during a usual two-week period; underlying medical problems; employment history during the two weeks before illness onset; and use of home air conditioning. At the end of the interview, case-patients were asked to identify two friends of the same sex as themselves and within 10 years of age to serve as control-subjects. Control-subjects were then telephoned, and the same questionnaire was administered. Risk factors were analyzed in a univariate fashion using the Pike-Morrow method for a variable number of controls per case without breaking the match.[3]

Results of the case-control study were used to focus subsequent investigation. Employees working within one-half mile of the retail store associated with cases of Legionnaires' disease, including the store itself, were asked to complete a questionnaire that requested information about recent illnesses and days missed from work. Serum speci-

mens were obtained from employees working in the implicated area and from control employees of similar age working at a similar retail store located 15 miles from the implicated area who volunteered to be bled. Antibody titers to *L. pneumophila* serogroup 1 were determined by standard methods.[4] Titers were compared by Fishers' exact test.[5]

Water samples were obtained from potential reservoirs of *Legionella* and cultured according to established protocols.[6] Methods used included filter concentration, acid treatment, and use of antimicrobial containing media.Soil samples were also obtained, hydrated in sterile water, and cultured by the same methods.

Records of precipitation and wind direction collected 3.7 miles from the implicated area were obtained from the National Oceanographic and Atmospheric Administration (Asheville, North Carolina), and the environment of the area associated with acquisition of Legionnaires' disease was inspected to determine whether any aerosol generating devices could be identified.

Results

Twenty-seven residents of county A developed Legionnaires' disease during May 1986, and two died. The dates of the onset of symptoms ranged from May 11 to May 28 (Figure 1). *L. pneumophila* serogroup 1 was isolated from two patients' sputa; lung tissue from a third patient, obtained post mortem, gave a positive direct fluorescent antibody stain for

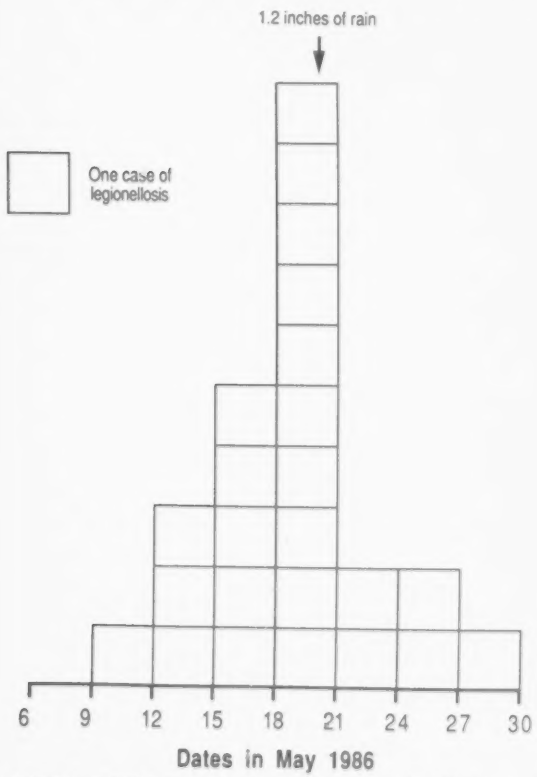

FIGURE 1—Date of Symptom Onset of Cases of Legionnaires' Disease (onset date unknown for 3 persons)

L. pneumophila serogroup 1; 11 patients had four-fold rises in reciprocal antibody titer to *L. pneumophila* serogroup 1, and 13 had reciprocal titers ≥256 (four patients had reciprocal titers of 256). The two isolates of *L. pneumophila* from patients with Legionnaires' disease gave the same monoclonal antibody binding pattern, binding to monoclonal antibodies 1, 2, 5, 7. Patients with Legionnaires' disease ranged in age from 27 to 80 years (median 51). Age-specific attack rates of disease, using 1982 estimates of the county's population, showed that although many young adults were affected, attack rates tended to increase with age (Table 1). Only 17.6 percent of the cases were in women. The locations of patients' residences were spread over a large geographic area, virtually the entire county, without clustering of cases by census tract (Figure 2).

In the case-control study, 16 patients with Legionnaires' disease and 28 controls were interviewed. Of the 27 cases of Legionnaires' disease, 10 did not meet the clinical criteria required for enrollment in the case-control study, and one could not be located. Twelve cases and four controls had visited store A in the two weeks before illness onset (lower bound 95% confidence interval 3.42). No other potential risk factor was significantly more common for the cases.

Store A is a large single room retail store employing approximately 100 employees situated in a sparsely populated area of County A with few nearby residences but some recent commercial development. Several hundred customers visit store A per day. Approximately 100 yards south of Store A, excavation and construction of a shopping mall took place during the month of the epidemic. No cooling towers or wet-heat rejection sytems were present within one-half mile of store A.

The survey of Store A employees revealed that one of 90 had had pneumonia during May. This individual had a reciprocal antibody titer to *L. pneumophila* serogroup 1 of 256 five weeks following the onset of his illness. Greater prevalence of detectable antibody to *Legionella* and higher titers were seen in Store A employees than in persons working in store B and near Store A (Table 2). Store A employees were 3.63 times as likely to have reciprocal titers of 256 or more (95% CI = 0.8, 16.7). Because of the delay between the survey and the end of the outbreak, it was not possible to obtain serum specimens or interviews from persons working at the construction site during May. No *Legionella spp.* were isolated from any of the 35 water and soil samples. The free chlorine level in potable water specimens was 1.0 parts per million.

Only 0.43 inches of rainfall were recorded for County A from May 1 through May 19, compared with a normal rainfall of 2.10 inches. At the peak of the outbreak, 1.2 inches of rainfall were recorded (Figure 1). The predominant wind direction during May (resultant wind vector) was from 241°,

TABLE 1—Attack Rates of Legionellosis in County A by Age*

from the southwest and toward store A from the construction site. Persons working in store A recalled extremely dusty conditions during May 1986, and review of the maintenance records for the ventilation system of store A revealed that frequent changes of the filters for the air intake had been required during the first three weeks of May. Store A was cooled with a freon-based, dry central air conditioning unit; there was no humidification of incoming air.

Discussion

Investigation of this Legionnaires' disease outbreak was complicated by logistic problems in obtaining and testing serum specimens that delayed laboratory confirmation of the diagnosis. We are unaware of previous Legionnaires' disease outbreaks occurring in rural areas despite serologic evidence that exposure is no less frequent in such areas.[7] Legionnaires' disease outbreaks in rural settings may be more difficult to identify because diagnostic facilities for legionellosis are frequently not available. Even in the context of epidemiologic study,[8] many patients with community-acquired pneumonia do not receive a precise etiologic diagnosis. Using review of radiograph reports to identify cases created additional difficulties in our investigation because of the low specificity of this method, unless combined with fever and white blood cell count.

Once Legionnaires' disease was identified as the cause of the outbreak, additional epidemiologic investigation demonstrated an association between visiting store A and illness. Results of the case-control study led to additional surveys to confirm the association of visiting store A and developing legionellosis. The attack rate of 1.5 percent in Store A employees is consistent with attack rates in other epidemics of Legionnaires' disease.[9,10] In addition, elevated antibody titers against *Legionella* were more common and these levels tended to be higher in employees of store A than in control populations.

Negative cultures of all environmental specimens, including water and soil samples, were not entirely unexpected since the specimens were obtained five weeks after the onset of the last case and the end of the outbreak. Since no evironmental legionellae were recovered, no microbiologic proof of the source of *Legionella* organisms was found in this outbreak. The absence of cooling towers at store A and the absence of exposure of case-patients to aerosols of potable water suggest that persons contracting Legionnaires' disease were exposed to some other source of *Legionnella* organisms.

Excavation and construction have been associated with outbreaks[10–12] and sporadic cases[13] of Legionnaires' disease, and excavation and construction of a shopping mall near store A occurred during the month of the epidemic. Although most outbreak investigations in which excavation and construction were associated with disease occurred before methods for recovering *Legionella* were available, in one nosocomial outbreak, *L. bozemanii* was recovered from potable water and from soil at a nearby excavation. *Legionella* was hypothesized to have colonized the potable water system at the time pipe connections linked the new building to the old.[11] Thus, in some outbreaks the link between excavation, construction, and Legionnaires' disease may be potable water.

In the current outbreak investigation cultures of potable water, although obtained five weeks after the end of the outbreak, were negative. High free-chlorine concentrations were found in the municipal water serving store A, so we doubt that *Legionella* could have survived in the potable water. Wind direction and the clogged air filters at store A suggest that airborne particles were blown from the construction site toward store A. Rains occurring on May 20, virtually the first rain of the month, coincided with a cessation of new cases after May 28, within the incubation period of Legionnaires' disease.

This temporal association is similar to that seen at the St. Elizabeth's Hospital outbreak in Washington, DC.[10] In that outbreak, attack rates of legionellosis for patients hospitalized in buildings near excavation were higher than the rates for patients not hospitalized near excavation. Because the etiologic agent was not discovered and methods to culture *Legionella* from the environment were not developed, the reservoir of *Legionella* was not determined. The tight temporal relationship between the onset of illness and excavation suggests that direct exposure to excavation was related to developing legionellosis.

Although legionellae have never been recovered from dry soil, they have been recovered from mud and wet soil.[11, 14–16] Since *Legionella* may be killed by heating or drying,[17] the hypothesis that legionellosis can occur after exposure to dry soil requires the assumption that *Legionella* may exist in an environment that provides protection from heating and drying. Additional environmental reservoirs for *Legionella* may be found in future studies, as were recently identified for *Blastomyces dermatitidis*.[18] The temporal relationship of the rains of May 20, and the cessation of new cases suggest that the rains halted the further transmission of *Legionella*.

This outbreak of Legionnaires' disease was associated with exposure to a retail store near a site of excavation and construction at a time when dry weather conditions prevailed. These results further suggest that, in some outbreaks,

exposure to construction and excavation may be a risk factor for Legionnaires' disease. Future investigations of Legionnaires' disease outbreaks associated with construction and excavation must include expanded searches for environmental legionellae and consideration of novel reservoirs.

Tuberculin Skin Testing in US Navy and Marine Corps Personnel and Recruits, 1980–86

ELEANOR R. CROSS, MS, AND KENNETH C. HYAMS, MD

Abstract: An extensive skin testing program is part of the United States Naval Medical Command's infectious disease control effort. From 1980 to 1986, 2,306,533 skin tests, using five TU PPD, were performed on active-duty Navy and Marine Corps personnel, 0.97 percent of which were positive. A downward trend in positive tests was found with a high of 1.43 percent in 1980 and a low of 0.80 percent in 1983. Since 1984, the percentage of positive tests has remained the same or increased. Shore-based medical facilities around the world reported 1,491,646 skin tests with 1.07 percent positive; Navy ships reported 814,887 skin tests with 0.78 percent positive. PPD-positivity for ships in the Pacific area was higher (0.98 percent) than for ships in the Atlantic (0.62 percent). During this same period, the percentage of positive tests in Navy and Marine Corps recruits ranged from a high of 1.82 percent in 1981 to a low of 1.23 percent in 1986. Since 1984, the percentage of positive tests has remained relatively stable in recruits. The frequency of positive PPD tests found in this study is lower than the percentage positive (1.59 percent) found in active-duty Navy personnel in 1969 and the percentage positive (5.2 percent) found in a study of Navy and Marine Corps recruits between 1958 and 1969. (*Am J Public Health* 1990; 80:435–438.)

Introduction

Since the early 1800s, the Medical Department of the US Navy has recognized the high transmission potential of tuberculosis.[1] Not only is there an increase in risk of exposure from world-wide travel but, as epidemiological studies have demonstrated, environmental conditions aboard ships are ideal for transmission.[2–4] Early attempts at TB control included screening sailors prior to an extended cruise and rejecting "all persons who were believed to be of unsound constitution."[1]

Today, the Navy's tuberculosis control program includes tuberculin skin test screening, contact investigation, and treatment of active cases and selected skin test reactors.[5] The Naval Medical Command directs all personnel whose previous test was negative to be periodically skin tested by the Mantoux method using 5 tuberculin units (TU) Purified Protein Derivative (PPD).[5] Annual screening is done on individuals assigned to operational units and to areas where possible exposure to tuberculosis is high, i.e., members of deployable Navy and Marine Corps units, shipboard personnel, and health care personnel. Sailors in low-risk areas, such as shore-based personnel in the United States, are tested every three years.

A person with induration measuring 10 mm or greater 48 to 72 hours after the administration of a 5 TU skin test is considered a "tuberculin reactor."[5] A new reactor is defined as "a person who has become a reactor within the past three years," and persons who are found to be reactors for the first time but whose prior tuberculin status is unknown. Since earlier studies indicated that a new reactor rate of 1 to 2 percent of personnel tested could be expected in many Navy and Marine Corps settings, the Naval Medical Command recommends a search for active cases of tuberculosis when the rate of new reactors exceeds 2.5 percent in groups of approximately 100 or more personnel.[5]

This report examines tuberculosis skin testing in the Navy from 1980 to 1986. Comparisons are made over time in and recruits Navy and Marine Corps active-duty personnel stationed in various geographic locations.

Address reprint requests to Eleanor R. Cross, Associate Investigator, Division of Epidemiology, Department of Infectious Diseases, Naval Medical Research Institute, 12300 Washington Avenue, Rockville, MD 20852. Dr. Hyams is Head of the Division of Epidemiology at NMRI. This paper, submitted to the Journal April 4, 1989, was revised and accepted for publication September 20, 1989.

Methods

Each month, all outpatient facilities of the Naval Medical Command report the number of PPD tests performed and the number of reactors. Information on age, sex, race, and the exact size of the reaction is not recorded, however. In this study, computerized files of skin test results for the period January 1980 to December 1986 were analyzed.

Reports are received each month from approximately 600 shore-based facilities and from over 500 ships. Approximately 25 percent of the shore-based facilities are located outside of the United States. It is important to note that the location of the reporting facility may not necessarily be the location of the tuberculosis contact. Data from shore-based facilities may include skin test results on individuals from ships during port visits as well as results on individuals transferred to a facility from a different location.

Although these tests are administered and read by a number of different medical personnel, the Naval Medical Command provides very specific instructions on the administration and reading of these tests.[5] Therefore, the overall results of the skin tests from different locations are generally comparable. Tubersol (Connaught, Inc., Swiftwater, PA) was used for the skin testing during the period of this study.

For the 1980 to 1986 study period, the total number of skin tests performed in active-duty personnel fluctuated from a high of 373,747 in 1983 to a low of 287,251 in 1986. Average annual active-duty strength increased from 720,832 in 1980 to 805,128 in 1986. Consequently, approximately 40–50 percent of the total force was tested annually. The mean age of active-duty personnel increased from age 25.0 years in 1980 to age 26.1 years in 1986. The mean sex ratio of Navy and Marine Corps personnel changed from 16:1 (male:female) in 1980 to 11:1 in 1986.

For recruit personnel, approximately 83 percent were between the ages 17 to 21 years during the study period. The percentage of both Black and Hispanic recruits increased during the period 1981 to 1986 from 12 percent to 17 percent for Blacks and from 4 percent to 9 percent for Hispanics.

Results

Between 1980 and 1986, a total of 2,306,533 tests were read for all active-duty Navy and Marine Corps personnel, 0.97 percent of which were positive. The rate of positive tests decreased from a high of 1.43 percent in 1980 to a low of 0.80

percent in 1983. In 1983, this downward trend changed, and from 1984 to 1986 the percentage of positive tests either remained the same or increased (Table 1, Figure 1).

Shore-based Facilities

In shore-based facilities located inside of the continental United States (CONUS), a total of 1,319,610 tuberculin skin tests were read, of which 1.00 percent were positive. The percentage of positive tests dropped from a high of 1.41 percent in 1980 to a low of 0.83 percent in 1983. After 1983, the rate of positive tests either rose or remained the same (Figure 2). The average percentage of positive tests in shore-based facilities located outside the continental United States (OCONUS) was higher (1.61 percent but followed a very similar trend (Figure 2).

By location of shore-based facilities, the highest frequency of positive tests was in the Philippines (3.10 percent), followed by Japan (2.90 percent), Korea (2.00 percent), Guam (1.88 percent), Bahrain (1.66 percent), and Okinawa (1.40 percent). By US Naval District, skin test positivity was highest in the Northwestern United States (1.79 percent) and Northern California (1.77 percent) (Table 1, Figure 3). The lowest rates were found in the North Central area (0.46 percent).

Positive TB Skin Tests Aboard Ships

Of 814,887 skin tests read aboard ships, 0.78 percent were positive. The positive rate was higher in ships based in the Pacific area (0.98 percent) than for ships based in the Atlantic (0.62 percent). As in shore-based facilities, there was a general downward trend in both areas from 1980 to 1982, especially in the Pacific. After 1982, the rates of positive tests remained fairly stable (Table 1, Figure 4).

Navy and Marine Corps Recruits

Between 1980 and 1986, a total of 618,074 skin tests were performed on recruits, 1.45 percent of which were positive (Table 1, Figure 5). The highest percentage of positive tests (1.82 percent) was found in 1981. Since 1984, the percentage of recruits with a positive PPD skin test has remained relatively stable at between 1.28 and 1.23 percent.

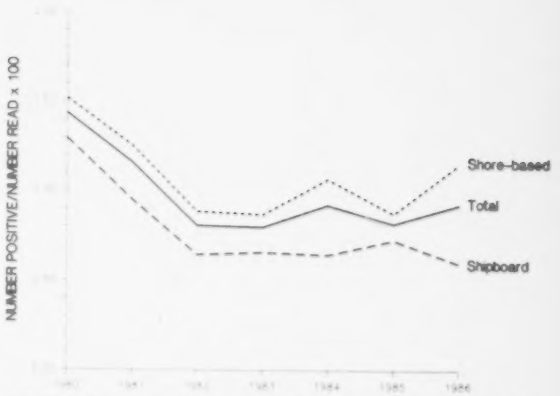

FIGURE 1—Frequency of Positive Tuberculin Tests in all Active-duty US Naval and Marine Corps Personnel, in all Shore-based Naval Medical Facilities, and in all ships, 1980–86

Discussion

The results of this study show a downward trend in the frequency of positive TB skin tests from 1980 to 1983. After 1983, the percentage of positive tests either remained stable or increased. It is noteworthy that these general trends occurred in all population groups of active-duty US Navy and Marine Corps personnel. The reason why different populations tested in different areas of the world exhibited such closely similar patterns of positive tests could not be determined. The data indicate, however, that the threat of TB infection is greatest in the Pacific for both shore-based and shipboard military personnel.

TABLE 1—Percent Positive Tuberculin Reactors in Active-duty US Navy and Marine Corps Personnel and in Recruits, 1980–86

Location	Number Reactors/Number Read × 100 (Reactors/Read)							
	Average 1980–86	1980	1981	1982	1983	1984	1985	1986
Total	0.97 (22388/2308633)	1.43 (4385/305837)	1.16 (3988/318616)	0.81 (2604/323488)	0.80 (2978/373747)	0.92 (3263/356926)	0.82 (2794/340588)	0.92 (2645/287351)
Shore-based								
Total	1.07 (16020/1491646)	1.52 (2908/191658)	1.25 (2750/219710)	0.88 (1927/218103)	0.87 (2158/248741)	1.07 (2481/233717)	0.87 (1847/211232)	1.15 (1939/168486)

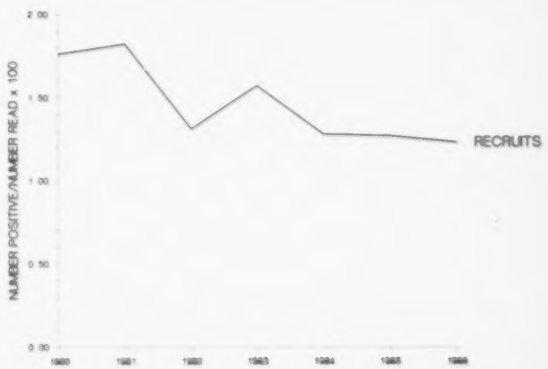

FIGURE 5—Frequency of Positive Tuberculin Tests in US Naval and Marine Corps Recruits, 1980–86

In 1969, 1.59 percent of skin tests were positive overall; 1.72 percent were positive in shore-based facilities in the continental United States; and, 1.08 percent of PPD tests were positive on Navy ships.[6] This level of skin test positivity is higher than for comparable groups during the 1980 to 1986 period of this study and suggests a continuation of the downward trend of tuberculosis infection in the US Navy which was observed prior to 1970.[7]

Between 1958 and 1969, Navy recruits were skin tested with 5 TU PPD by specially trained public health nurses.[7] Tuberculin reactions measuring 10 mm or greater were found in 5.2 percent of the tests. This is substantially higher than the percentage of positive tests (1.45 percent) found in recruits from 1980 to 1986 and corresponds to the lower incidence of tuberculosis in the United States during the period of the current study.

One problem when comparing positive skin test rates in military personnel is that an unknown number of tests are applied but not read, which would lower overall rates. However, there is no reason for this problem to have been greater in any location or any particular year of this study. Also, a person with a positive skin test who is missed on one screening has another chance of being detected on subsequent testing and counted as PPD-positive.

There was a steadily declining incidence rate of tuberculosis disease in the US civilian population until 1984. In 1986, for the first time since 1953, there was a substantial increase in indigenous tuberculosis cases.[8] This reversal has been attributed to an increase in the number of cases of acquired immunodeficiency syndrome (AIDS); to an increase in the number of tuberculosis cases in the homeless, immigrant and other susceptible populations; and, to decreased tuberculosis control efforts.[8–10]

The military population in this study also demonstrated a change in the declining incidence of tuberculosis infection at the time tuberculosis disease was increasing in the civilian population. The military population, however, does not include a large number of individuals who are particularly susceptible to tuberculosis infection, such as the homeless or immigrants, although AIDS cases have been reported in the military.[11,12] Also, the highest rates of positive tests observed in this study occurred in shore-based facilities outside the continental United States, where events occurring in the US may have had less impact.

Factors which could have changed the extent of TB exposure in the military, such as increased deployment to and increased recruitment from endemic regions such as the Philippines, could not be analyzed from the available data.[7,13,14] However, no large shipboard tuberculosis out-

breaks of the magnitude previously reported occurred during this seven-year study period.[2,3]

The "booster effect" is a phenomenon in which increases in the size of the skin test reaction is due to boosting of waned hypersensitivity by sequential testing rather than new infection. Boosting is more common among middle-aged and older persons and when skin testing is done at frequent intervals.[15,16] Because the Naval Medical Command recommends annual testing for personnel in high risk areas and retesting every three years for those personnel at low risk, boosting should be uncommon except in frequently tested groups such as hospital personnel.

5th National Conference on Chronic Disease Prevention and Control

The Centers for Disease Control, the Association of State and Territorial Health Officials (ASTHO), and the Directors of State Chronic Disease Programs will cosponsor the fifth national conference on "Chronic Disease Prevention and Control: From 1990 to 2000," October 17–19, 1990 at the Westin Hotel, Renaissance Center, in Detroit, Michigan. The conference is open to the public; there will be a $25 registration fee.

The 1990 conference will include two plenary sessions that address demographic trends:
- Implications for Chronic Disease and the Public's Health
- Tobacco Control: Science and Politics

Six concurrent sessions of invited papers will focus on special populations:
- Minorities, the Elderly, and Rural
- State Highlights—A Look at Michigan
- Quality of Life and Disability—Issues and Impact
- Dietary Fat/Nutrition
- Industry and Chronic Disease Prevention—What Are the Societal Roles and Responsibilities?
- State and Community Tobacco Control Activities

The conference will consider abstracts for oral presentations, poster sessions, or roundtable discussions on relevant chronic disease topics involving: program development and implementation; epidemiologic studies; and social and economic issues.

For additional information, contact: Jack Friel, MPA, Chief, Conference Management Operations, Center for Chronic Disease Prevention and Health Promotion, Mailstop A37, Centers for Disease Control, Atlanta, GA 30333; (404) 639-2249 FAX (404) 639-1563.

Tuberculosis Infection in Urban Adolescents: Results of a School-based Testing Program

M. Anita Barry, MD, MPH, Lillian Shirley, RNC, MPH, Michael T. Grady, MD, Sue Weidhaas Etkind, RN, MS, Carol Almeida, BSN, John Bernardo, MD, and George A. Lamb, MD

Abstract: In 1986–87 a pilot tuberculosis (TB) skin testing program was introduced for seventh and tenth grade students in the Boston (Massachusetts) public schools. The 8.9 percent tuberculin positivity rate in tenth grade students was significantly higher than the 5.1 percent rate found in seventh graders. A majority of those who were skin test positive were born outside the United States. These results suggest that tuberculin testing in an urban school setting may identify a significant number of candidates for TB preventive therapy, particularly among tenth grade students and those who are foreign-born. (*Am J Public Health* 1990; 80:439–441.)

Introduction

Tuberculosis (TB) continues to be an important public health problem in the United States. In 1986, 22,768 cases of tuberculosis were reported nationwide, including 1,214 (5.3 percent) in children younger than 15 years of age.[1] In 1987, nine of 123 verified TB cases in Boston, Massachusetts occurred in children under age 15.[2]

Development of active TB can be largely prevented by isoniazid (INH) therapy in infected persons without disease.[3] However, identification of both adults and children with TB infection is problematic. Current guidelines from the American Academy of Pediatrics for TB testing in children advise annual tuberculin testing in high-risk children, such as those in neighborhoods where the TB case rate is higher than the national average, those from households with one or more cases of TB, American Indian and Alaskan children, and children of parents who have immigrated from Asia, Africa, the Middle East, Latin America, or the Caribbean.[4] In low-risk groups, TB skin testing is recommended at 12–15 months of age, before school entry, and in adolescence. However, no recent published data on the prevalence of tuberculous infection in urban adolescents in the United States are available to assess whether adolescents should be considered at high risk.

Following the diagnosis of TB in a Boston Public School student in the fall of 1986, a TB testing program was introduced for seventh and tenth grade students. Students with positive skin tests were referred for appropriate medical evaluation and preventive therapy. The purpose of this report is to describe the prevalence of tuberculin skin test positivity in seventh and tenth grade students who participated in the program as well as the subsequent course of preventive therapy in those for whom such therapy was indicated.

Methods

The Boston Public School system enrolls approximately 57,000 students. Seventh graders are enrolled in 25 middle schools, and tenth graders in 19 high schools with each school assigned either a full- or part-time nurse. Racial-ethnic breakdown reveals that 47.8 percent of all Boston Public School students are Black, 25.6 percent White, 17.7 percent Hispanic, 8.2 percent Asian, and <1 percent other.

At the time this program was introduced, TB testing was required for new school entrants only. The new policy continued to require TB testing for new school entrants (regardless of grade). In addition, seventh and tenth grade students not previously known to be PPD (purified protein derivative) positive were required to have a TB skin test done during that school year. Due to problems of retention and motivation of urban adolescents in school, however, students were not excluded from classes if they did not comply with the seventh and tenth grade testing policy. Students were encouraged to have tuberculin testing performed by their primary care provider, but arrangements for placement and reading of skin tests in the schools were made. Mantoux testing using intermediate strength PPD was the preferred method for skin testing as suggested by the Centers for Disease Control (CDC) and the American Thoracic Society guidelines.[5] Tubersol (Connaught Laboratories Inc., Swiftwater, PA) was the only PPD product used within the schools. Medical evaluation and a single chest x-ray following a documented positive skin test were mandatory.

Data collected for each tuberculin positive student included information on age, sex, race, country of origin, site of testing, size of PPD induration, site of medical follow-up, and duration of INH therapy. For analysis, chi square testing was used (Professional Database Analysis System; Conceptual Software, Inc., Houston, Texas).

Results

Of 3,642 seventh graders eligible, 2,799 (77 percent) were tested (Table 1). In the tenth grade 2,584/4,353 (59 percent)

TABLE 1—Results of a Tuberculosis (TB) Testing Program, Boston Public Schools, 1986–87

	Grade 7	Grade 10
Number eligible	3,642*	4,353*
Number (percent) tested	2,799 (77)	2,584 (59)
Number (percent)** PPD positive***	145 (5.1)#	233 (8.9)

*This number excludes 34 and 29 known PPD positives in seventh and tenth grades, respectively.
**Numbers include those previously known to be PPD positive.
***PPD positive is defined as induration ≥ 10 mm at 48–72 hours.
#Difference in proportions is 3.8 percent (95% CI = 2.5, 5.2) using test-based confidence interval.

participated in the program. Participation rates in individual schools ranged from 33 percent to 100 percent in seventh grades and from 16 percent to 100 percent in tenth grades. Of seventh grade program participants, 1,554 (56 percent) were tested in school and 1,245 (44 percent) by their private health care provider. Of tenth graders, 1,881 (73 percent) were tested in school and 703 (27 percent) by a private provider. The rate of tuberculin positivity in seventh graders (5.1 percent) was substantially lower than that in tenth graders (8.9 percent) (see Table 1).

Mean age of seventh graders who tested positive during the program was 13.1 years (range 12 to 15 years); 85 percent were foreign-born. The mean age of tuberculin positive tenth graders was 16.5 years (range 14 to 21 years); 80 percent were foreign-born (Table 2). Country of origin was documented for 295 tuberculin positive students (Table 3). The largest number were from Caribbean countries with Haiti the most common country of origin.

Information on the size of PPD induration was available for 131 of the 315 students with induration ≥ 10 mm. Twenty-four percent had a reading ≥ 20 mm; an additional 13 percent had induration between 16 and 19 mm.

Records to assess compliance with preventive therapy were available for 230 of 314 (73 percent) tuberculin positive students (Table 4). Overall 63 percent of students for whom preventive therapy was recommended completed at least six months of therapy.

An unexpected finding during the program was the discovery of an unsuspected case of active pulmonary TB. The individual was an asymptomatic 20-year-old Haitian male in the tenth grade whose tuberculin test had been negative two years previously. His chest x-ray, done in follow-up to a 25 mm PPD in school, revealed right upper lobe infiltration consistent with active or old TB. Sputum smear was negative. Isoniazid, rifampin, and ethambutol therapy was started. When cultures revealed *M. tuberculosis* sensitive to all antimicrobial agents tested, ethambutol was discontinued. In the high school he attended 41 percent of the tenth grade students participated in the program. Thirty-three (18 percent) of these were tuberculin positive.

Discussion

In 1979, data from 13 cities with populations of 250,000 or greater revealed a tuberculin positivity prevalence of 5.6 percent in those ages 5–14 years.[6] In our study, the 8.9 percent rate of tuberculin positivity found in tenth graders whose mean age was 16.5 years was substantially higher than the 5.1 percent found in seventh graders whose mean age was 13.1 years. There are several possible explanations for the higher rate in tenth graders. There may be proportionately more foreign born tenth graders than seventh graders; data to document this possibility are not available. Second, the higher rate may be related to more advanced age and consequently a longer chance to become infected. Third, higher rates in tenth graders may have occurred as a result of spread from the tenth grade student with unsuspected Class III pulmonary TB. However, the case was not smear positive, and excluding results from his school lowers the prevalence rate in tenth graders only to 8.3 percent (200/2405).

Generalizability of tuberculin prevalence rates noted in this study to all urban adolescents is limited by several factors. Rates in students may differ from those in adolescent drop-outs and student non-participants. Although data are available for 59 percent of tenth graders and 77 percent of seventh graders, little is known about those who chose not to

participate. Finally, Boston is a gateway city for refugees; this may result in higher rates of tuberculin positivity than in cities where refugees are less common.

Delivery of adequate preventive therapy, defined as ≥ six months of INH, could be documented in a greater proportion of seventh graders than tenth graders (74 vs 59 percent). These figures are comparable to the 73.4 percent completion of preventive therapy figure noted by CDC among all persons for whom preventive therapy was recommended over a 12-year period in 16 selected regions of the US.[7]

Current TB surveillance practices in the United States vary widely. A 1983 survey of health department officials revealed that only 20 percent of respondents required TB screening in students.[8] The authors concluded that testing of students was non-productive other than "in schools with large numbers of refugees, immigrants, children of indigent parents, etc." The proportion of urban school systems which meet such criteria is unknown, and data from other geographic regions are needed to resolve the issue.

In the United States, TB rates are higher in minorities. In 1986, the TB case rate per 100,000 population was 4.6 in Whites, 17.7 in Hispanics, 27.6 in Blacks, and 50.4 in Asian/Pacific Islanders.[9] Our tuberculin positivity rates reflect this trend with the highest prevalence in Asians, followed by Hispanics and Blacks.

Using data from an analysis done by the Centers for Disease Control in 1986,[10] the cost effectiveness of this program can be demonstrated. Assuming progression to active TB in 10 percent of those not receiving preventive therapy, and $4,983 cost for a single uncomplicated case of disease, the cost of preventable cases detected in this program would be $189,384. In contrast, the actual cost of the screening was $75,465 ($19,000 for a part-time nurse coordinator, $1,057 for screening supplies, and $55,408 for the clinical and pharmaceutical costs related to INH follow-up) for a net savings of $113,919.

Preventable TB cases continue to occur in children in the US.[11] Our data suggest that TB testing in urban school settings comparable to ours is likely to uncover a significant number of adolescents who are tuberculin positive. Because of the relatively high risk of progression to active tuberculosis in adolescents who are infected with TB, identification of and therapy for tuberculin positive children and adolescents is particularly important.[12]

ACKNOWLEDGMENTS

The authors would like to acknowledge the support of the following individuals whose efforts were essential for this project: Boston Public School students and personnel, particularly the school nurses; TB Control staff, Boston Department of Health and Hospitals; Mary James-Neher, Josie Ford, Ed Nardell, MD and Lynne Mofenson, MD, Massachusetts Department of Public Health; Annette Forbes, Community Infectious Disease Epidemiology Program, Boston Department of Health and Hospitals. This study was presented in part at the 116th Annual Meeting, American Public Health Association, November 13–17, 1988, Boston, MA.

AAFP Will Publish Family Practice Research Journal

Family Practice Research Journal is now an official journal of the American Academy of Family Physicians (AAFP), signifying the Academy's efforts to support clinical research by family physicians. The Academy recently assumed ownership from Sciences Press, a subsidiary of Plenum Publishing Corporation, New York. *American Family Physician* also is a medical journal of the Academy.

According to the publisher, Clayton Hasser, "*Family Practice Research Journal* aims to complement other family journals by focusing on the stimulation and renovation of clinically oriented, practice-initiated and practice-based research articles, with emphasis on assisting novice family physician researchers and authors to implement and publish their research studies." Currently published twice a year, the journal will become a quarterly publication beginning with the June 1990 issue.

The American Academy of Family Physicians, headquartered at 8880 Ward Parkway, Kansas City, MO 64114, is the national association of family doctors. It is the largest national medical specialty organization with more than 68,000 members. The Academy was founded in 1947 to provide high continuing medical education standards.

Epidemiologic and Clinical Characteristics of Persons with Serologic Evidence of *E. canis* Infection

BARTON W. ROHRBACH, VMD, MPH, JOHN R. HARKESS, MD, S. A. EWING, DVM, PHD, JERRY KUDLAC, MPH, GARRY L. MCKEE, PHD, AND GREGORY R. ISTRE, MD

Abstract: The results of a serosurvey of Oklahomans for the presence of antibody to *Ehrlichia canis* is reported. Paired serum specimens, from patients lacking the serologic criteria for diagnosis of Rocky Mountain spotted fever (RMSF), were tested. A four-fold increase in *E. canis*-IFA antibody was found in 16/144 (11 percent) of these paired serum samples. Patients with serologic evidence of *E. canis* infection had a mean age of 34 years, 69 percent were male, and 63 percent lived in a town <10,000 population. Signs and symptoms included: fever 94 percent, headache 94 percent, fatigue 94 percent, anorexia 81 percent, nausea 60 percent, and rash 44 percent. When compared to control patients, whose sera were submitted for RMSF testing but did not meet serologic criteria for RMSF or *E. canis*, case-patients were more likely to have had leukopenia (OR = 4.9, 95 percent CI = 1.2, 19.0) and tick exposure (OR = 9.5, 95 percent CI = 1.4, 62.7). The results suggest *E. canis*, or a closely related agent, is a cause of human illness. Ticks are a probable vector. (*Am J Public Health* 1990; 80:442–445.)

Introduction

In each of the years 1982–86, Oklahoma has had the highest rate of Rocky Mountain spotted fever (RMSF) in the United States. For every case of RMSF reported, at least four other persons were tested for RMSF, but were negative for RMSF antibody.[1] We have suspected that these illnesses, which we have called "Oklahoma tick fever," may be caused by other tick-borne agents.[1]

Ehrlichia canis is the causative agent of canine ehrlichiosis, a tick-borne, rickettsial disease of dogs with wide geographic distribution.[2,3] In 1986, the first case of human infection with *E. canis* was described.[4] The patient was bitten by several ticks 12 days before onset of illness and was initially suspected to have RMSF. The diagnosis of *E. canis* infection was made from electron micrographs of leukocytic cytoplasmic inclusions characteristic of *Ehrlichia* species, and the presence of an eight-fold fall in serum antibody titer to *E. canis* during the seven weeks following onset of illness. Since discovery of the first case, additional patients have been identified, by serologic testing, from at least 11 states.[5–9] Although *Ehrlichia canis* has not been isolated under natural conditions from species other than *Canidae*, current evidence supports the role of *E. canis*, or a closely related agent, as a cause of illness among human beings.[2]

We undertook a case-control study to link clinical characteristics and risk factors with serologic evidence of *E. canis* infection.

Methods

Case Surveillance

To identify patients with serologic evidence of *E. canis* infection, we tested paired (acute- and convalescent-phase) sera from 144 persons. The survey included all available paired serum specimens that were tested for *R. rickettsii* in Oklahoma during 1986 and found negative. We obtained sera from the Oklahoma State Department of Health (OSDH) and a commercial hospital laboratory located in Oklahoma City. Using an indirect fluorescent antibody test (IFA), the convalescent-phase specimen for each pair was screened for *E. canis* antibody at 1:16 dilution. For patients whose sera was positive at 1:16, the acute- and convalescent-phase specimens were tested in consecutive two-fold dilutions until an end point titer was reached. A positive test result was defined as a four-fold or greater increase in antibody titer to *E. canis* antigen, and a peak convalescent-phase titer of ≥1:64.

Sera from patients with positive tests for *E. canis* were also tested for antibodies to *Rickettsia typhi* and *Coxiella burnetti* by microagglutination test at the Rocky Mountain Laboratories, Hamilton, Montana.[10] All available blood smears from case-patients, made during their illness, were examined for leukocytic intracytoplasmic inclusions. Blood specimens obtained from dogs belonging to case-patient households were tested for *E. canis* antibody at the Oklahoma Animal Disease Diagnostic Laboratory, Oklahoma State University, Stillwater.[11] Three ten-fold serum dilutions beginning at 1:10 were tested for each dog specimen.

Case-Control Study

We compared the epidemiologic and clinical characteristics of the 16 patients with positive tests for *E. canis* with 32 controls randomly selected from the 128 RMSF-IFA negative patient serum pairs remaining after case-patients had been identified. Controls were matched by laboratory from which the case-specimen originated, and consisted of patients whose acute- and convalescent-phase serum was <1:64 for *R. rickettsia* and convalescent-phase serum <1:16 for *E. canis*.

Efforts were made to conduct personal interviews for case-patients and controls. Substitute control-patients were randomly chosen from the remaining controls when it was not possible to complete interviews with the initially selected controls. Interviews began with open-end questions and concluded with questions designed to elicit specific clinical and demographic information and animal and arthropod exposure histories. All available medical records were reviewed for cases and controls. Odds ratios (OR) and 95%

confidence intervals (CI) were calculated using the program developed by Rothman and Boice.[12]

Laboratory Procedure

A standard IFA procedure for detecting antibody to *R. rickettsii* had been used by both laboratories from which RMSF-negative serum was obtained.[13] All testing of human serum for *E. canis* antibody was done at the Oklahoma State Department of Health (OSDH) laboratory using a commercially available *E. canis* antigen (ProtaTek International Inc., St. Paul, Minnesota*), and according to a published procedure[11] with the following exceptions: human serum was substituted for canine serum, dilutions started at 1:16, a quantitative control was used, and goat anti-human conjugate (Clinical Sciences, Wippany, New Jersey*) was substituted for anti-dog conjugate. A random sample of case-patient sera was blindly retested for *E. canis* antibody by OSDH laboratory personnel. Agreement was confirmed if the second test result was within one dilution of the first result.

Results

Case Surveillance

Of 144 serum pairs tested, 16 (11 percent) had a four-fold increase in antibody titer to *E. canis* antigen (Table 1). The geometric mean titer for case-patients increased during each successive week for the first month after onset. An agreement of 80 percent between the first and second test result was recorded when 10 of the serum specimens were blindly retested for *E. canis* antibody.

Case Description

The mean age of case-patients was 34 years (range 2–68), and more than two-thirds were male (Table 2). Most case-patients lived in a town of less than 10,000 population or a rural unincorporated area, and all but one case-patient recalled finding one or more ticks on their body during the 30 days before onset of illness.

Signs and symptoms most frequently experienced by case-patients included fever, headache, fatigue, anorexia, and nausea (Table 3). Rash was present in 7/16 (44 percent) patients, and was described as petechial (three patients), maculopapular (three patients), or vesicular (one patient). When present, rash was limited to the trunk and proximal extremities; no case-patient had rash involving hands or feet.

Results of 43 total leukocyte counts performed on 15/16 (94 percent) case-patients were evaluated. Leukopenia, (WBC <4,800/mm^3), was observed in 10/15 (67 percent) case-patients. Excluding patient #4, whose onset date is uncertain, the median day after onset of clinical signs for the lowest total leukocyte count was day 4 (range 0–11 days) for the remaining nine case-patients who had leukopenia. Of 35 total lymphocyte counts available for 14 case-patients, lymphopenia, (<1,500/mm^3), occurred in 9/14 (64 percent), and

Platelets <150,000	5/13 (38)	4/18 (22)	2.2	(0.4, 14.1)

*Denominator may be less than 16 due to missing information.
†Denominator may be less than 32 due to missing information.

excluding patient #4, the median day after onset of illness for the lowest lymphocyte count was 6.5 (range 0–15 days). Platelets were evaluated in 13 case-patients, five (38 percent) of which were thrombocytopenic, (<150,000/mm^3). A total of 21 platelet counts were performed on the five thrombocytopenic case-patients, and the median day after onset for the lowest platelet count was 6 (range 3–16 days).

Of seven case-patients for whom data were available, five (71 percent), had serum aspartate aminotransferase (AST) values above the reference range (0–0.58 ukat/L). Serum from six of these patients was also tested for total bilirubin, and in two patients (Nos. 8,9 Table 1) the values were 6.6 and 2.2 mg/dL, respectively.

Sufficient paired serum was available from 13/16 (81 percent) case-patients to test for antibodies to *Rickettsia typhi* and *Coxiella burnetti*. No significant titers (>1:8) were detected to either antigen. Microscopic examination of peripheral blood smears from three case-patients and a buffy coat smear from a fourth, made during clinical illness, did not reveal inclusions characteristic of *Ehrlichia* spp.

Illness resulted in hospitalization for 6/16 (37 percent) case-patients, and tetracycline or chloramphenicol was prescribed for all but two. There were no case-patient deaths.

Two case-patients were diagnosed with other illness. One 12-year-old boy (No. 8) had vomiting, jaundice, petechial rash, and a positive IgM-specific anti-HAV test diagnostic of recent hepatitis A infection; the other, a 39-year-old male (No. 11), had fever, fatigue, posterior cervical adenopathy, and a four-fold decrease in antibody titer to Epstein-Barr virus supporting a diagnosis of mononucleosis. A third case-patient (No. 4) developed a chronic illness with fatigue, myalgia, and a vesicular rash on his arms, head and mouth two to four weeks after removing a tick from his abdomen. One month after onset he received a 10-day course of tetracycline 250 mg QID. Serum specimens drawn 84, 99, and 140 days after onset revealed no antibodies to *R. rickettsii* but elevated titers to *E. canis*. The cause of illness in the remaining 13 case-patients was either unknown or clinically thought to be RMSF despite negative serologic tests.

Of 25 dogs in 14 case-patient households, we tested 16 (64 percent), from nine households, for *E. canis* infection and none had antibody titers, ≥1:100, suggestive of recent infection.

Case Control Study

All cases, and 27/32 (84 percent) controls were interviewed in person by one or two of the authors (BWR and JRH). Cases and controls were informed of serologic results prior to interview. Of 32 original controls, two were deceased, two had moved out of state, and one could not be contacted. Information for the two deceased controls was obtained from medical records, and telephone interviews were conducted for three others, two of whom had moved out of state and one for whom personal interview was impractical due to constraints of time and distance.

The median interval of time from onset of disease to collection of acute- and convalescent-phase serum was similar for cases (median = 4 and 18.5 days, respectively), and controls (median = 3 and 17 days, respectively). Case-patients were slightly older, more often male, and somewhat more likely to live in a town of <10,000 population or a rural unincorporated area than were controls (Table 2).

Signs and symptoms in case-patients were similar to those of controls except for an increased frequency of headache reported by case-patients. Case-patients were more likely to have developed leukopenia (WBC <4,800/mm^3) and to have reported finding a tick on their body in the month before onset of illness both of which were statistically significant (Table 2). Exposure to bloodsucking arthropods other than ticks was similar for case-patients and controls except that controls were more likely to report flea bites.

Discussion

Our findings support the role of *E. canis*, or an antigenically similar agent, as a cause of clinical illness among humans in Oklahoma. We have demonstrated serologic evidence of *E. canis* infection in a subgroup of Oklahomans whose serum was submitted for RMSF testing, but that did not meet the criteria for serologic confirmation. Laboratory findings of leukopenia, lymphopenia, and elevated hepatic enzymes in both canine [14] and human[4–9] patients are consistent with the hypothesis of a common agent. The similarity of clinical characteristics among case-patients and the differences between case-patients and controls support the hypothesis that the case-patient syndrome is a distinct clinical entity.

E. canis is reported to have a limited host range,[2] and the only recognized vector, *Rhipicephalus sanguineus*, feeds infrequently on humans.[15] This suggests the possibility of an antigenically similar, but distinct, agent as the cause of illness in case-patients, or an unrecognized mechanism of transmission for *E. canis*.

The proportion of *E. canis* positive serum pairs in the sample tested (16/144, 11 percent) when applied to the total number of serum specimens found negative for RMSF in Oklahoma each year implies that the incidence of human ehrlichiosis may be as much as half that of RMSF. The frequency with which evidence of infection was found in Oklahomans and the wide distribution of *E. canis* in the United States suggests that other states should consider

surveillance to determine the presence and distribution of infection.

Further studies are necessary to assess the sensitivity, specificity, and reliability of the canine IFA test for humans. Our results, on a limited sample, demonstrated an 80 percent reliability. The two case-patients with confirmed diagnoses of hepatitis A and mononucleosis may reflect on the specificity of this test. Based on the antibody response of all other case-patients, the rise in titer for patient No. 4 between days 88 and 94 after the reported onset of illness suggests the possibility of concomitant illness and a more recent exposure to *E. canis* antigen.

Clinical characteristics of case-patients were markedly similar to patients with RMSF and to controls. Oklahomans with symptoms of fever, headache, rash, and a history of tick-bite during the period April through August will prompt submission of samples for RMSF testing. Clinical characteristics among case-patients could be biased as a result of selection for RMSF and may not be representative of the disease as it exists in the general population. Differences such as the increased frequency of low white blood count in case-patients, when compared to controls, are likely to be valid. Rash occurred less frequently in case-patients than in controls, and when present was not of the typical pattern described for RMSF.

The results of this study implicate ticks as vectors for transmission of infection to case-patients. In spite of a selection bias for increased frequency of tick exposure in the population from which both case-patients and controls were drawn, a significantly higher proportion of case-patients reported finding ticks on their body than did controls. Previous reports indicate 50 percent to 100 percent of patients with serologic evidence of *E. canis* infection had tick exposure.[5-9] The recognized vector for *E. canis* in dogs in the United States, *R. sanguineus* (the brown dog tick), is reported to feed on humans infrequently suggesting that this species is of questionable importance in transmission of infection to humans. When the agent of human ehrlichiosis is isolated from a human patient, further studies of other tick vectors are indicated. If the agent is identified as *E. canis*, then the possibility of chronic infection of humans should be investigated, as chronic *E. canis* infection has been documented in dogs.[16]

ACKNOWLEDGMENTS

This study was supported in part by the Oklahoma Center for the Advancement of Science and Technology. We are indebted to the many Oklahoma physicians and hospital personnel for their cooperation in allowing us to review medical records for patients included in this study. We also appreciate the assistance of Dr. Rebecca Morton of the Animal Disease Diagnostic Laboratory, Oklahoma State University; Dr. Tom Schwan of the Rocky Mountain Laboratory, United States Public Health Service; Dr. Kathrine Kocan of the Department of Pathology, College of Veterinary Medicine, Oklahoma State University; and Sue Hannon and Robin Botchlet of the Immunology Laboratory, Oklahoma State Department of Health.

New *Hospice Magazine* Seeks Feature Articles, Other Materials

Hospice Magazine—a new quarterly publication of the National Hospice Organization—is seeking original articles by hospice professionals which convey the daily life, community atmosphere, and sense of mission in the hospice field from the perspective of those working in it. Suggestions for article topics include: "slice-of-life" stories from the hospice care setting; hospice trends; profiles of hospice professionals; developments in pain and symptom, and quality assurance controls; working with hospice volunteers; fund-raising approaches; training techniques; wound care; and more. The style and tone of *Hospice Magazine* are intended for a broad readership, therefore purely technical or scholarly articles are not being sought. Regular articles should be between 1,000 and 2,000 words; materials for other departments about 500 words, i.e., profiles, new products and information sources, model projects and programs, humorous/anecdotal information, book reviews, etc.

For further information, contact the Editor, *Hospice Magazine*, National Hospice Organization, 1901 North Moore Street, Suite 901, Arlington, VA 22209. FAX: (703) 525-5762. Telephone inquiries regarding article ideas or submissions should be made to Joseph Cerquone, (703) 548-0382.

Self-Rated Health and Mortality in the NHANES-I Epidemiologic Follow-up Study

ELLEN L. IDLER, PHD, AND RONALD J. ANGEL, PHD

Abstract: The ability of self-rated health status to predict mortality was tested with data from the National Health and Nutrition Examination Survey (NHANES-I) Epidemiologic Follow-Up Study (NHEFS), conducted from 1971–84. The sample consists of adult NHANES-I respondents ages 25–74 years (N = 6,440) for whom data from a comprehensive physical examination at the initial interview and survival status at follow-up are available. Self-rated health consists of the response to the single item, "Would you say your health in general is excellent, very good, good, fair, or poor?" Proportional hazards analyses indicated that, net of its association with medical diagnoses given in the physical examination, demographic factors, and health related behaviors, self-rated health at Time 1 is associated with mortality over the 12-year follow-up period among middle-aged males, but not among elderly males or females of any age. (*Am J Public Health* 1990; 80:446–452.)

Introduction

A rather intriguing and consistent finding concerning the predictors of mortality has been reported by several researchers in recent years. Studies based on four different sets of data indicate that a simple, one item self-report of health status is as powerful a predictor of mortality as more detailed health status indicators.[1–3] In these studies the response to some variant of the question, "Would you say your health is excellent, very good, good, fair, or poor?" is significantly associated with the risk of mortality over periods of four to nine years, even when prior information about health and all other major known risk factors are accounted for. Without good baseline health indicators, this finding would not be particularly surprising. But the varieties of methods used and the consistency of the findings in these studies leads to the rather profound realization that what we learn from this simple question carries a great deal of clinically relevant information, making it as powerful a predictor of mortality as simultaneous reports of serious chronic disease or functional disability.

The first of these studies was published in the *American Journal of Public Health* in 1982.[1] In it, Mossey and Shapiro reported that in a large elderly Canadian sample of the province of Manitoba, respondents' self-ratings of health outweighed the extensive health care utilization and medical history data available in predicting survival over a seven-year period. The editor of the Journal, realizing the importance of the finding, highlighted it in an accompanying editorial.[4]

Subsequent studies in California, Connecticut, and Iowa have replicated the finding. Adults in Alameda County, California, who assessed their health as poor had increased relative risks of mortality of approximately 1.95 compared to those who said they were in excellent health, even when self-reports of chronic and acute illnesses, sex, age, income, education, health practices, and social networks were controlled.[2] Elderly adults in New Haven, Connecticut, and Iowa and Washington Counties, Iowa, had increasing risks of mortality for every level of self-assessed health other than excellent, despite controls for chronic conditions, disability, pain, medications, demographic factors, and health practices.[3] Together, these studies suggest that individuals have access to very important internal information with which they are able to make informed predictions of their probability of survival.

The primary methodological problem that makes attempts to assess the medical significance of self-reported health status difficult arises from the inability to unambiguously control for actual physical health status. In models in which self-assessments are used as predictors of some outcome, their impact may in fact be due to inadequately measured physical health status. In other words, it is difficult to establish that self-assessed health has an influence above and beyond that it shares with actual physical health. The studies mentioned above all took different approaches to isolating the net effect of self-assessed health, but all of these controls for physical health relied heavily on the self-reports of respondents and, as a result, none could be considered ideal controls for "objective" health status. Even the Canadian study, which depended to a smaller extent on respondent information, substituted records of medical care utilization which the authors acknowledged were subject to biases of their own.[1,4] No population-based study of self-assessed health and mortality has had as its physical health status control the results of a comprehensive, standardized physical examination carried out by trained physicians. Such an examination could be considered objective because it would consist of observations made by an external and impartial observer, and because a single standard would be applied to all participants in the study. Only this form of measurement would have the possibility of detecting untreated, undiagnosed, and otherwise unreported conditions.

Methods

Such a methodology is precisely the one employed by the National Center for Health Statistics's National Health and Nutrition Examination Survey (NHANES-I),[5] conducted from 1971 to 1975, and the NHANES-I Epidemiologic Follow-up Study (NHEFS),[6] conducted from 1982 to 1984. Specifically, the NHANES-I provides data from a detailed physical examination of a 20 percent subsample of the first-stage NHANES-I sample (N = 3,854), and an additional sample which is called the augmentation component (N = 3,059); together these make up a baseline sample of 6,913 adults ages 25 to 74 years who constitute a probability sample of the United States population. The first-stage NHANES-I sample deliberately oversampled certain population subgroups believed to be at risk for nutrition-related health

problems: persons living in poverty areas, women of childbearing age, and the elderly. This sample is thus simultaneously very heterogeneous and nationally representative.

The follow-up to the NHANES-I, the NHEFS, successfully traced 92.9 percent of the original NHANES-I cohort;[7] for the subsample analyzed here the proportion traced was slightly higher, 93.2 percent. Those who were lost to follow-up tended to be younger, especially Black males and White females.[7] Respondents are included in the present analysis if they were successfully traced (by being contacted in person or having a proxy and/or a death certificate to verify their death), regardless of whether or not they completed the follow-up interview. This yields a usable sample size of 6,440. We might note that tracing over 90 percent of the sample 10 years after the initial survey is a truly commendable feat and it makes these data one of the best sources available for studying the predictors of mortality. The death rate for the subsample was 12.9 percent, somewhat lower than the 15.1 percent reported for the total sample.[7] This is likely due to the fact that the augmentation component was added to the sample at the end of the NHANES-I data collection period, thus making follow-up periods shorter for a substantial portion of our sample. The outcome variable used in this study is survival time following the initial interview.

The NHANES-I and the NHEFS are ideal for our purposes because they contain a fully objective source of information on the respondent's medical diagnoses at Time 1, as well as the respondents' self-ratings of health. The physicians made direct physical examinations of the respondents, including standing and sitting blood pressure and pulse, examination of the ears, head, eyes, mouth, neck, abdomen, major and minor joints, and skin, percussion of the liver, and auscultation of the heart. Based on positive responses to screening questions, the physician then administered supplemental questionnaires for arthritis, respiratory, and cardiovascular diseases. In addition, the physicians had immediately available to them the results of the following laboratory and other tests: hemoglobin, hematocrit, red and white blood cell counts, height and weight, body and skinfold measurements, audiometry, spirometry, electrocardiogram, single breath diffusing capacity, goniometry, and X-rays of the chest, hand and wrist, hips and knees.[5] The examination is as detailed as one could reasonably expect in a population survey of this scale. The physicians recorded their findings by coding any abnormalities they found in terms of the International Classification of Diseases Revision Eight (ICD-8) categories[8] and judged the severity of these conditions on a three-point scale as either minimum, moderate, or severe.[9] To create a set of variables which would summarize this information we grouped the ICD diagnosis codes by the ICD's own 15 broad categories: infectious diseases, cancers and neoplasms, metabolic disorders, blood diseases, mental disorders, diseases of the nervous, circulatory, respiratory, digestive, and genitourinary systems, diseases of the skin and musculoskeletal systems, congenital anomalies, symptoms of ill-defined conditions, and accidents.*

An individual received a score of one for that category if they had one or more diagnoses present; the score was then weighted by one, two, or three for the most severe grading the physician had given that individual for any diagnosis in that ICD category. Respondents were scored zero if they received no diagnosis in a category. In addition, to account for the additive effects of comorbidity, we created a variable that consists of the sum of unweighted separate diagnoses each respondent received. This complete set of variables is introduced first into all models as a control for medical diagnoses. It represents a distinct alternative to the methods used in previous studies in that it distills a large amount of information from a comprehensive physical examination that was conducted by a small team of physicians in a structured and standardized manner, and it incorporates a weight for the clinical severity of the condition, a feature which even the most accurate or extensive self-report data cannot claim.

Certainly a physical examination of the sort administered in the NHANES-I is not unerring. In a single cursory examination, the physician is likely to miss subtle conditions or syndromes in their prodromal state. Diagnosis is a complex task that depends on the physician's judgment and any single assessment of a person's state of health is always subject to observer variability.[10] The examination represents no more than the physician's informed clinical judgment arrived at after a brief encounter with a new patient. However, because the examination was performed by an external, independent, medically trained observer, and because these observers relied on standardized criteria for assessing the presence or absence of specific conditions, these diagnoses avoid confounding the impact of self-rated health on mortality with that of self-reported controls for health.

The independent variable of primary interest in this study is the response to the single item, "Would you say your health in general is excellent, very good, good, fair, or poor?" The question wording used here, and the labels for the five response categories differ slightly from those used in other studies;[1-3] in some cases the categories are excellent, good, fair, poor, and bad; sometimes only four categories are included and "poor" is omitted; sometimes the eliciting question contains a relativizing phrase such as "compared to other people your age . . ." The significance of these alternate forms in unknown; however, to date no two published studies have used the same form, although all have reported similar effects. Because of low frequencies in the "poor" category, the "poor" and "fair" categories were combined in this analysis, reducing the five response categories to four; the responses are treated as a set of n-1 dummy variables with the omitted category being "excellent" health.

The following sociodemographic variables are included in the analysis as controls: age (treated as a continuous variable); and dummy variables for race, 9 to 12 years of education or 13 or more years (compared with 8 or fewer), marital status, income less than $5000, income less than $15,000, and being currently employed. Health behavior variables included dummy variables for current smoking and past smoking (compared with never having smoked); an index of alcohol use based on the frequency of consumption multiplied by the number of drinks usually consumed, weighted by their alcohol content; the physician's indication of the presence of obesity; and a measure of inactivity based on frequency of exercise and other physical activity.

Proportional hazards models based on the SAS statistical procedure PHGLM[11,12] are used to estimate the effect of self-rated health on the probability of survival during the follow-up period. This procedure was used because of the censored nature of the data and because we wish to identify the predictors of survival time over the entire follow-up period. A complete, parallel set of logistic regression analy-

*Two additional categories, for pregnancy complications, and perinatal morbidity and mortality, were omitted as irrelevant and of negligible frequency.

ses on the dichotomous mortality outcome was also performed, which in effect measured the probability of survival at just one time point, the end of the follow-up period. The results of these logistic regressions were nearly identical to those from the survival analyses, hence we present only the latter. Odds ratios are calculated from the hazard models by taking the antilog of the estimated coefficients.[13] Three models are estimated, one containing just the physician's examination variables and self-rated health, one which adds sociodemographic variables in a block, and a third which adds health behavior variables. In this way, any changes in the relation between self-assessed health and mortality can be attributed to the various control variables.

Results

Figures 1 and 2 show the unadjusted relationship between self-assessed health at the time of the first interview and the probability of survival over the 12-year follow-up period for men and women. These figures show that: 1) mortality risks increase for individuals with progressively poorer self-perceptions of health; and 2) the risks are apparently greater for males than for females. Only 60 percent of males with poor self-assessed health survive to the end of the 12-year period, while nearly 80 percent of the women do. Further, the lines are more straight than curved indicating that the increased risk of mortality is spread throughout the follow-up period. Because of the differences in the risk of mortality, all analyses are performed separately by sex.

The full proportional hazards models are presented in Tables 1 and 2. In the first models, which contain only physician examination variables as controls, self-assessed health explains a significant amount of the remaining unexplained variation in survival time; odds ratios for the extreme category are 3.3 for men and 2.1 for women. There are also progressively elevated risks for the intermediate categories for men, but not for women.

The models which add sociodemographic variables reveal a diminished effect of self-assessed health on mortality for men, with lower odds ratios of 1.7 for poor/fair health and 1.5 for good health. Among the women all effects of self-rated health disappear. Stepwise logistic regressions not shown here reveal that age accounts for most of the association between self-assessed health and mortality for men and for all of the association for women. In this sample older people were more at risk for both poor self-assessments of health and mortality. Among the males, some of the apparent initial

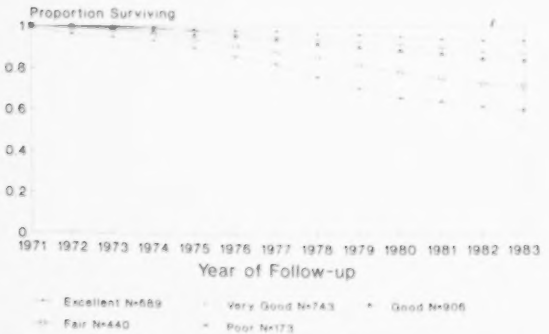

FIGURE 1—Male Mortality in NHANES-I Epidemiologic Follow-up Study by Levels of Self-rated Health

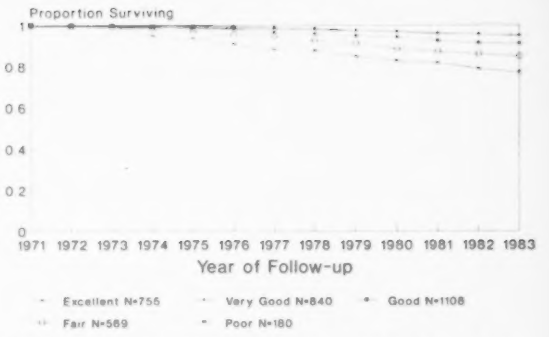

FIGURE 2—Female Mortality in NHANES-I Epidemiologic Follow-up Study by Levels of Self-rated Health

effects of self-assessed health on mortality were also due to confounding effects of employment, marital status, and race. Taking all these variables into account reduces the odds ratio for the extreme category by half.

It should be noted that the model with sociodemographic factors taken into account fits the data much better than the model with health variables alone. The models' likelihood ratio chi squares (G^2) reported at the bottom of Tables 1 and 2 double when these variables are added, and the difference in G^2 is highly significant (588.2, 27 df - 285.9, 19 df = 302.3, 8 df, $p < .000$ for men; 429.0 27 df - 211.8, 19 df = 217.2, 8 df, $p < .000$ for women).

The third model introduces variables for smoking, alcohol use, obesity, and lack of exercise. The inclusion of these factors does not alter the already nonexistent relationship for women. It further reduces the association for men, so that only the extreme category contrast remains. A second stepwise procedure (not presented) revealed that the addition of current smoking to the model had the biggest impact on the association; males who smoke were both more likely to give poor self-assessments of health and to die. The final adjusted odds ratio for the poor/fair category in the men's hazard model is 1.5 (95% CI = 1.1, 2.2).

These models too have a substantially better fit than the sociodemographic models which preceded them. Adding the measures of health behaviors adds 54.1, 5 df ($p < .000$) to the G^2 for men, and 12.3, 5 df ($p < .05$) for women.

Given the literature on the ways in which self-ratings of health vary according to the respondent's social location, certain interactions were considered. We have already seen that self-rated health predicts mortality marginally for men, but not at all for women. But does it predict mortality better for some men (or women) than others? The issue of age is especially salient given that so many of the previous studies have been done with elderly samples. To test an age-self-rated health interaction, we divided the males and females into three groups, those ages 25 to 44, 45 to 64, and 65 to 74. Because deaths were extremely rare (31 males and 27 females) in the under-45 age group, making parameter estimates from these models unreliable, we do not report the results from the youngest group.

The results can be seen in Tables 1 and 2. A substantial difference emerges between the middle-aged and elderly men. The relation between self-rated health and mortality for the male sample as a whole disappears altogether for elderly men, and emerges very strongly for middle-aged men. In the

latter group, odds ratios for the poor/fair, good, and very good categories are 2.8 (95% CI = 1.5, 5.3), 2.2 (95% CI = 1.2, 4.1), and 1.9 (95% CI = 1.0, 3.7), respectively. Self-rated health does appear to predict mortality very strongly for middle-aged men and it predicts better for them than for any other group.

Because we were interested in the relative contributions of the self-rated health and physician examination variables to the explained variance in mortality, we compared the fit of the full models (Model 3 in Tables 1 and 2) with the fit of models from which we had alternately removed the variables for self-assessed health and physician-assessed health. This would allow us to assess the relative contribution of the two health status measures by their contribution to the G^2 for the full model. We estimated these models for the whole sample, and also by age group. Our findings varied, both by sex and by age, and were somewhat surprising: for the women in the sample, neither the physicians' diagnoses nor self-assessed health make any significant contribution to the model G^2 when sociodemographic and health behavior variables are controlled. While some of the individual physician measures were significant predictors of female mortality (notably diagnoses of circulatory and mental disorders), the removal of the entire set of diagnoses from the model failed to reduce the G^2 by a significant amount. For the males, on the other hand, the physician measures (diagnoses of circulatory and respiratory disorders, and ill-defined illness symptoms in particular) did contribute to G^2, both for the male sample as a whole (642.3, 32 df - 606.2, 16 df = 36.3, 16 df, $p < .01$) and for the elderly men (95.3, 32 df - 57.5, 16 df = 37.8, 16 df, $p < .01$). In none of these groups did the block of self-assessed health variables have an impact on G^2. Among the middle-aged men, however, where the effect of self-assessed health on mortality was strong, self-assessed health does alter G^2 (186.6, 32 df - 174.8, 29 df = 11.8, 3 df, $p < .01$). The effect of the physician-assessed measures within this group is marginal (186.6, 32 df - 162.0, 16 df = 24.6, 16 df, $.10 > p > .05$). These comparisons corroborate the findings regarding the importance of self-assessments of health among middle-aged men, and show the findings from the physicians' examinations to be better predictors of male mortality than female mortality.

To focus a little more closely on the role of self-assessed health vis-a-vis the other important predictors of mortality, we compared the odds ratios and partial Rs for the various levels of self-assessed health with those for other variables in

the full models. For the male sample as a whole, age is the most important predictor of mortality, followed (in this order) by smoking, unemployment, alcohol use, illness symptoms, marital status, race, respiratory diagnoses, poor self-assessed health, circulatory diagnoses, low income, and lack of exercise. Among the middle-aged men, poor self-assessed health ranks fourth as a predictor, behind (in this order) alcohol use, age, and smoking. Among the women the order is age, circulatory diagnoses, race, marital status, smoking, unemployment, and mental disorders. We conclude that health behaviors (especially smoking and high levels of alcohol use) and demographic variables (particularly employment) are more important predictors of mortality in age-adjusted models than either physician- or self-assessed health. Among the physician measures, however, we would note that ill-defined illness symptoms, and diagnoses of respiratory and circulatory problems are the best predictors of mortality for men, and diagnoses of circulatory and mental disorders are most important for women.

In understanding the impact of self-rated health on mortality, one of the other concerns has been that poor self-assessments of health may simply be reflecting the greater severity level or better respondent knowledge of conditions which are leading to imminent mortality.[1] If people with poor self-assessed health only survive for a short follow-up period then the effects of self-assessed health are more easily explained as inadequate controls for physical health status than as indicators of some more subtle process.

To test this possibility, we identified deaths which occurred in three "early mortality" periods of two, three, and five years following the year in which the respondent entered the NHANES-I study, and compared them with the deaths that occurred in the remaining years. We then performed logistic regression analyses with the full set of variables on just the subset of deaths to see if self-assessments of health predicted early mortality better than late mortality. The results (not shown) revealed that, among both males and females, self-rated health did not predict early mortality better than late. This confirms the findings of Mossey and Shapiro,[1] who concluded that ". . . while objective health status may change over time, self-ratings of health represent a relatively stable perception held by the individual." (p 804) This suggests that the effects of self-assessed health on mortality cannot be explained by superior respondent knowledge of the poor prognoses for existing conditions that are leading to imminent mortality.

Discussion

These analyses have shown that the ability of self-rated health to predict mortality in this national sample is in large part explained by the sociodemographic characteristics, health risk behaviors, and the medical diagnoses of the respondents. Only among middle-aged men was there any substantial independent increased risk of death from self-assessments of health after these other factors were taken into account. In this NHANES-I sample, older people, smokers, alcohol abusers, the unmarried, the unemployed, and Blacks were initially less likely to give positive assessments of their health and subsequently less likely to survive, and these factors, by and large, account for the initial association of self-rated health with mortality.

Our findings, then, do not fully corroborate the findings of the earlier studies reviewed above in which self-assessments remained strongly significant predictors of mortality in full samples, in spite of controls for physical health indicators and other factors. Our analysis differs from these earlier studies in two major respects: 1) the NHANES-I provides an alternate indicator of physical health, medical diagnoses; and 2) the analysis is based on a large and heterogeneous national sample. The previous studies were of localized and/or elderly samples, and employed controls for physical health status that were at least in part based on self-reports. We attribute the differences between our results and those of previous studies to these differences in study design.

No other population-based prospective study of self-assessed health has had medical diagnoses derived from a standardized medical examination as statistical controls for physical health status. The NHANES-I detailed examination could potentially yield information on previously undiagnosed as well as treated and self-reported illness. Indeed, this was a primary purpose of the NHANES-I: ". . . to obtain information on unrecognized and undiagnosed conditions—in some cases, even nonsymptomatic conditions."[5] (p 3) In studies which depend on self-reports of conditions for their measure of physical health status, the same optimistic or pessimistic response bias may influence specific reports of conditions as well as global assessments. The current study is unique in basing its controls for physical status on information gathered from an external observer and hence applies the same standard to all respondents, regardless of their race, income status, education level, or access to medical care.

Having said this, it should be noted that however theoretically advantageous these controls for medical diagnoses are, they do not on their own eliminate the association of self-assessed health with mortality in this sample. In fact, they explain very little of the observed variation in survival. Perhaps this should not be surprising; this was a fundamentally healthy young and middle-aged sample and few cases of serious illness were diagnosed. Moreover, in making their diagnoses, the physicians were not asked to consider longevity as a criteria. In any case, among both men and women, self-assessed health remained a strong predictor of survival when the diagnoses alone were controlled. In this analysis, the relationship of self-assessed health to mortality was better explained by age (primarily) and, to a lesser extent, by smoking, alcohol abuse, unemployment, race, and marital status than it was by its confounding with physical health status as judged by these physician examinations.

The second major difference between the present study and those which have preceded it concerns the sample. The NHANES-I sample is large and heterogeneous, quite unlike the community, county, or even provincial samples discussed earlier. One concrete example of the differences is in the role that age plays in the analyses. In the Connecticut and Iowa samples,[3] which contained only elderly respondents, age acted as a suppressor variable on the relation between self-assessed health and mortality; that is, because older (elderly) respondents gave better self-assessments of health at any given level of objective health status than younger (elderly) respondents, controlling for age in the analysis *increased* rather than decreased the effect of self-assessments on mortality. In the NHANES-I sample of young and middle-aged adults and only relatively young elderly, the effect of age is very much the opposite: adding a main effect of age to the models sharply curtails or eliminates the association of self-assessed health with mortality.

Only in one age/sex group do we see the hypothesized effect. In a sense, however, this is the group for which the public health significance of the findings is potentially greatest, since male mortality in this age group greatly exceeds female mortality, and since most deaths which occurred in this group could be considered premature and conceivably preventable. The limited findings in this study may provide some clue to the origins and meaning of these subjective perceptions. One might speculate that the apparently accurate predictions of survival made by the middle-aged male respondents in this study could be derived in part from a knowledge of their family's history. Having had a close family member who suffered a premature death from heart disease or cancer could lend ominous significance to symptoms such as a persistent cough or a mildly high cholesterol level which might appear unimportant to someone from a long-lived family. One might also observe that the strength of the association in this age group underscores the fact that, in our society, "excellent" health is the norm for the nonelderly, and any deviation from the norm indicates a potentially serious risk.

Even in comparison with the urban and nonelderly Alameda County sample with which it has more in common, however, the NHANES-I sample is diffuse and geographically unbounded. It encompasses the complex ethnic and cultural diversity of the nation. The cognitive processes by which individuals make global judgments about internal states are by no means well understood, but there is strong evidence that they somewhat consistently vary from one social, ethnic, or cultural setting to another.[14–17] Self-assessments appear to be made by some process of reference-group comparison, in which the individual chooses an appropriate group and judges the state of his or her own health by the health levels typical of the group in question. In other words, these judgments have no absolute reference point. The national sample in a sense removes these judgments from the cultural and community contexts in which they were formed, causing the variation in mortality to be explained primarily by the more objective and also more diverse physical health, demographic and health behavior factors. This analysis should remind us that demographic and health risk behavior factors remain potent predictors of mortality.

Self-assessments of health should continue to be of interest as mortality predictors, not only within homogeneous community samples, but also in large national samples where their impact appears more limited. Self-ratings of health are inexpensive, easy to obtain, and already available in nearly all health surveys. Even if they act as sensitive indicators of mortality risk only for certain subgroups in the population, they should remain valuable tools for health researchers.

Lowell Levin to Edit New International Journal

Lowell S. Levin, EdD, MPH, professor of public health at the Yale University School of Medicine, has been named editor of the new *International Journal of Iatrogenic Complications*. The quarterly journal, associated with the Copenhagen-based International Society for the Prevention of Iatrogenic Diseases, will begin publishing in February 1991.

Dr. Levin explains that although "iatrogenic" translates literally as "physician-produced," the study of such problems has come to emcompass the negative consequences brought on by any segment of the increasingly complex health care system. When a part of that system harms a patient either by accident, negligence or imcompetence, the ramifications go beyond the medical, to the legal, social and economic. Hence, each article submitted to the new periodical will be reviewed by a jury of three readers from various disciplines, rather than the two readers used by many journals. In addition to physicians, the reviewer roster will include attorneys, economists, social scientists, epidemiologists and others, drawn from a broad geopolitical spectrum.

Dr. Levin is an internationally recognized authority in the field of self-care, which emphasizes education to empower the public in health matters and to prevent illness. He has helped pioneer this concept in both the developed and developing worlds, and has served on various World Health Organization (WHO) committees, including the WHO Committee on Information and Education for Health.

Scholars or other researchers who would like to submit articles to the *International Journal of Iatrogenic Complications* may contact Dr. Levin at (203) 785-2849.

The Economic Impact of Injuries: A Major Source of Medical Costs

LINDA C. HARLAN, PHD, WILLIAM R. HARLAN, MD, AND P. ELLEN PARSONS, PHD

Abstract: Data from the 1980 National Medical Care Utilization and Expenditure Survey were analyzed to place the costs for injuries in the context of all medical costs and to describe the distribution by demographic and diagnostic groups. For the non-institutionalized population, injuries, which include intentional and unintentional, were the second leading cause of direct medical costs, accounting for $16,745 million in medical care expenditures and a major contributor to work loss and disability in the US. For the working-age population (17–64 years) injuries were the leading cost category ($11,341 million) and the third most costly category for persons 65 years of age and over ($3,479 million). The preponderance of costs were attributable to hospital-based care. Direct medical costs were disproportionately greater for males, White and other persons, and for those with household incomes less than $5,000. Injury morbidity also accounts for major indirect costs. Fractures accounted for the highest direct medical costs, greatest per capita charges (based on those with charges), and largest number of restricted activity days. These national estimates document the economic importance of injuries and direct public attention to policy imperatives related to research and prevention. (*Am J Public Health* 1990; 80:453–459.)

Introduction

Injuries are the most common cause of death in the United States for persons under the age of 44.[1] In 1986, unintentional injuries ranked as the leading cause of years of potential life lost before age 65.[2] This consideration and the high incidence of injuries and consequent disability have directed public attention to this problem.[1-3] Despite the frequency of accidental injury, there is a relative paucity of national data on medical costs and morbidity. There appears to be a major disparity between health costs (both direct and indirect) and research investment for prevention and management.[1] However, valid estimates of the national economic impact have not been available until recently[4,5] and these total estimates do not provide a full understanding of the impact of accidents and injuries in various age-sex groups. Information on direct medical costs and indirect costs from disability could provide an economic perspective that would buttress recommendations for greater public investment in research in this field.[1] Moreover, the distribution of costs across demographic and diagnostic categories affords a background understanding of utilization that could lead to focused efforts at prevention and cost containment.

To provide a picture of the national expenditures for injuries, we have analyzed data from the 1980 National Medical Care Utilization and Expenditure Survey (NMCUES). This survey provides the most recent national data on the costs of injuries, which include both intentional and unintentional injuries.

Methods

NMCUES, national survey of health expenditures and use of personal health services, was conducted by the National Center for Health Statistics and the Health Care Financing Administration during 1980 on a national sample of the civilian, non-institutionalized population of the United States. The survey included persons living in 6,600 households. The sample design was a multi-stage probability sample drawn from 135 primary sampling units representing the 50 states and the District of Columbia. Data on 17,123 persons were collected from February 1980 through April 1981. Data were analyzed for Whites and others in one racial category and Blacks in another. The "other" category included American Indians, Alaskan Natives, Asians, and Pacific Islanders. These individuals accounted for approximately 2.5 percent of the "White and other" category. The effect of "others" in the "White and other" category would be expected to be very small. Approximately 7 percent of the NMCUES sample reported themselves as Hispanic. The sample weight was constructed based on race, not ethnicity. The Hispanics are distributed across the racial categories, most being in the White racial category. The estimates obtained if Hispanics were analyzed separately would be non-representative.

Interviews were conducted with each household at approximately three-month intervals. The first two interviews were conducted during a personal household visit by an interviewer; the next two were conducted by telephone; and the final interview was a personal household visit. At the first interview, the respondent was given a diary and asked to record occurrences, conditions, and functional impairments. In addition, the respondent was to record all charges for illnesses and injuries irrespective of who paid these charges, i.e., Medicare, Medicaid, private insurance, or out-of-pocket expenses. Subsequent telephone and personal interviews focused on these diaries. The final response rate was 87.9 percent when attrition over the course of interviewing was taken into account. Detailed information on the survey design, sampling bias, instruments, and statistical analyses are available in several monographs.[5-8]

The public use files of NMCUES were used for these analyses after edits were performed as outlined in the NCHS methodological monograph.[7] Conditions were coded using the International Classification of Diseases, ninth revision, ICD-9[9] and special NCHS codes[10] and grouped into 18 broad diagnostic categories. This report focuses on the "injuries and poisonings" category. In this report, these are referred to as "injuries." The injury category comprised the diagnostic groupings and the relevant ICD codes shown in the Appendix.[9] Both intentional and unintentional injuries are included in these analyses. It was not possible to determine from the data the cause of the injury.

Direct costs for these analyses were defined as charges incurred and reported for inpatient and outpatient care,

physician and allied health services, prescribed medication and selected medical equipment and other services. The reports of costs were not verified so it is likely that there was an underreporting of actual charges. Some groups probably underreported their charges more than others. Individuals covered by Medicaid, General Assistance or Veterans Administration benefits may not be informed by the payer of the actual charges and may thereby underestimate charges more than other groups.[5] In addition, these data include information only on civilian, non-institutionalized individuals. Costs related to individuals in hospitals, nursing homes, and other institutions or the military would not be represented here.

Disability attributable to these diagnostic groups was categorized into restricted activity (usual activity restricted by illness), bed disability (confined to bed more than half a day), and work loss (lost work because of illness). Restricted-activity days is the most inclusive category and include bed-disability days. Bed-disability days include all hospital days, even if a bed was not occupied. The complex sample design, sampling and respondent biases, and entry or attrition from the survey during the survey year were taken into account in the analysis using procedures described in a methodological monograph.[7] Use of these procedures permits national estimates to be made.

Results

Direct Costs

Direct medical costs for injuries comprised the second largest source of expenditures for medical care in the United States during 1980 (Figure 1). The estimated $16.8 billion for injuries represents 12 percent of all direct costs. This amount was exceeded only by an estimated $20 billion in charges for diseases of the circulatory system.[5]

The distribution of medical costs for the four leading condition categories is presented by age groups in Figure 2. Injury and poisoning ranked among the top cost categories for three of the four age groups (<17 years, 17 to 44 years, and >65 years). Injury costs were the greatest ($9 billion) for young adults (17 to 44 years). This diagnostic category was the third largest contributor to medical costs for older Americans (65 years and over) and was exceeded only by costs related to circulatory conditions and neoplasms. When only the working-age population (17–64 years) was considered, full-time or part-time workers had injuries and poisonings as their major source of medical costs. In contrast, persons not employed had greater charges from other diagnostic categories, generally chronic diseases.[6]

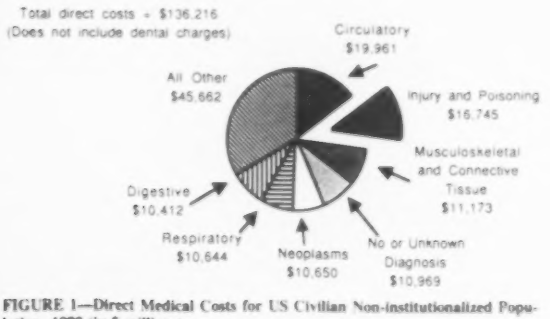

FIGURE 1—Direct Medical Costs for US Civilian Non-institutionalized Population, 1980 (in $ millions)
SOURCE: National Medical Care Utilization and Expenditure Survey

The proportion of medical costs attributable to injuries are presented by demographic characteristics in Figure 3. Medical costs for injuries are presented as the proportion of total direct medical costs for each referent group; the denominator is the total direct cost for all conditions for that group. Injuries accounted for a greater proportion of medical costs for males than for females. White and other persons also had proportionately greater medical costs attributable to injuries than did Black persons. The distribution of injury costs across income groups indicates that persons with family incomes less than $5,000 had a greater proportion of medical costs attributable to injuries than did those in the other income groups. The lower income group (<$5,000) comprised 7.3 percent of the total population, but their total injury costs accounted for 10.3 percent of all injury costs. Thus, the lowest income group had disproportionately greater costs for injuries and disproportionately higher health care expenditures.

The injury category was separated into 11 diagnostic groups which followed the ICD-9 diagnostic categories. The direct costs were determined for each of these groups. The costs attributable to each diagnostic group are presented in Table 1, as are the distributions by age group, sex, and race. Fractures, which includes skull fractures, were responsible for the greatest expenditures and generated $6.4 billion in charges or almost 40 percent of total costs for injuries. The early treatment of trauma ($2.6 billion) and management of the late effects of trauma ($1.7 billion) were also major sources of costs. Sprains and dislocations, wounds (including blood vessel injuries) and complications of medical and surgical care were the only other diagnostic groups leading to over $1 billion per year.

There were important variations in diagnostic group costs by age, sex, and race (Table 1). The costs attributable to fractures, the most costly category, varied by age group from 27 percent (<17 years) to 43 percent (>65 years). Fractures accounted for more costs for females (42 percent) than for males (35 percent). Black persons had 44 percent of injury costs attributable to fractures in contrast to 38 percent for White and other persons. The costs associated with early treatment of trauma were highest for the 45 to 64 year old group, for females, and for Black persons. This grouping includes multiple traumatic injuries, but excludes specific traumatic diagnoses such as fractures and burns. Costs associated with later effects of trauma were greatest for those over age 65 years, for females, and for White and other persons. Sprains and dislocations generated relatively low charges for those over 65 and for females. Wounds accounted for 21 percent of costs for those under 17 years and wounds and fractures together accounted for almost half (48 percent) of costs in this age group. Poisoning costs were overwhelmingly associated with females and were highest in the 17 to 64 year old group. Costs for burns were higher for males than for females and for those 45 to 64 years.

The immediate cause of the injury (e.g., vehicular accident, fall, attempted suicide, etc.) and contributing causes (e.g., alcohol ingestion, speeding, etc.) were not recorded in NMCUES. Therefore, only indirect inferences can be made about causation. The distribution of injuries suggest a relatively greater cost impact of trauma, i.e., sprains, wounds and head injuries, from leisure and work activity on young males and greater cost impact on older women from fractures and late sequelae of trauma.

These aggregate direct costs do not disclose the costs on a per occurrence or per person basis or the allocation of costs

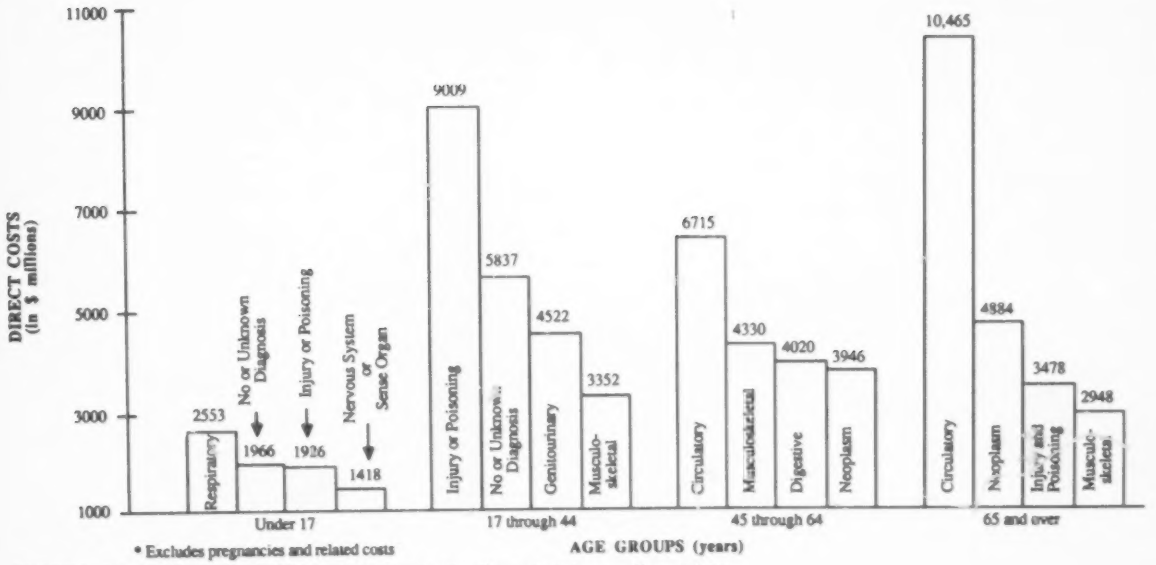

FIGURE 2—Direct Medical Costs for All Persons by Four Leading Diagnostic Categories, Cost, and Age

across components of care. Therefore, the per capita charges were determined for the diagnostic categories and divided into the charges for four types of health services: hospital care (including emergency room), ambulatory medical care (including outpatient physician charges), hospital physician charges, and medication charges (Table 2). The per capita charges are based on mean cost per individual having charges under each diagnostic and health service category. On a per capita basis, the highest charges were for management of the late effects of trauma and for fractures. For the other diagnostic groups, the rank order of per capita charges differed somewhat from the rank order of total direct charges (Table 1). Sprains had relatively low per capita costs but high aggregate costs because of greater frequency. On the other hand, burns had high per capita costs but low aggregate costs. The most striking finding regarding per capita charges is that the preponderance of charges for each diagnostic code (except sensory impairment) were generated by hospital care, which includes emergency room services. However, for the diagnostic categories of foreign bodies, burns, and sensory impairment, the estimates are unstable because fewer than 10 individuals in NMCUES were hospitalized in each category during the survey. The next highest category of charges were for physicians' hospital services. Only small charges ranging from $12 to $71 were reported for medications and from $57 to $224 for ambulatory care. Therefore, over 90 percent of per capita costs for most injury categories were related to hospital-based care.

Disability

Disability and work loss are indirect morbidity costs of medical conditions. Although total disability, work loss, and restricted-activity days were collected on each individual, a single day could be assigned to several conditions. Therefore, days lost for each condition were calculated by multiplying the weighted proportion of days lost due to the condition of interest by the total days lost. A national estimate of 932,300 person years of restricted activity and 292,300 person years of bed disability were attributable to injuries. These days represent about 10 percent of days attributable to all conditions during 1980 and exceed the estimates of disability for circulatory conditions for the same period.[11]

Restricted-activity and bed-disability days are presented for the diagnostic groups in Figure 4. Fractures were responsible for the greatest mean number of restricted-activity and bed-disability days at all ages. For persons age 65 years and older, the mean number of days approximately doubles. Similarly, two- to three-fold greater disability occurred for older adults with head and internal injuries, late effects of trauma, and complications of medical and surgical care. For sprains, burns, and early effects of trauma, there were no differences by age. On the other hand, poisonings, sensory impairment, and wounds had lower mean days of restricted activity or bed disability for older persons, but the frequency

was low and the estimates unstable. In general, bed-disability days comprise less than half of restricted activity except for those over age 65 years who had fractures, head and internal injuries, and late effects of trauma. Although not reported here, the distributions of disability by gender and race were similar to the distributions of direct and per capita costs.

Work-loss days were estimated for the working age-population (17 to 64 years), both men and women. The total work loss attributable to injuries was 247,900 person years. This represents 14 percent of all work-loss days attributable to illness. The mean work-loss days by diagnostic groups are plotted in Figure 5. Fractures were responsible for the highest mean work-loss days. Sensory impairment, head and internal injuries, sprains, burns, and the early and late effects of trauma are the other injuries that resulted in a mean work loss of five days or more. There were important differences between men and women for several of the condition groups. Men had more work-loss days than women from all conditions except sensory impairment and fractures. Although not shown, there were no important trends by race, except for greater mean work-loss days for Black persons attributable to early and late treatment of trauma.

Discussion

These analyses confirm that injuries are a major source of medical costs, both direct medical charges and indirect costs of illness, as measured by disability days. Injuries are the second leading cause for direct medical costs in the civilian, non-institutionalized population. This cost burden is spread across all ages. Injuries are the leading contributor to medical costs for persons 17 to 44 years of age. Importantly, injuries also account for a considerable proportion of medical costs for Americans, age 65 years and over. For this older group, only circulatory conditions and neoplasms are responsible for higher costs. The general perception that medical expenses in older, non-institutionalized persons result primarily from chronic diseases and infections contrasts with these national findings.

These survey data underestimate the actual economic impact on the elderly because NMCUES did not survey institutionalized persons who represent an important proportion (about 10 percent) of those over age 65 years. As such, NMCUES does not address the cost burden related to institutionalized individuals. Hodgson and Kopstein have reported that the costs for this group are different than those living in the community.[4] Using a variety of data sources, they estimated that per capita expenditures for the elderly institutionalized and non-institutionalized population rank injuries as the 4th and 8th, respectively for women and men. These authors also found that although only 11 percent of the population is over the age of 65, they consume about 31 percent of the personal health care dollars. Therefore, the total cost estimates for the US population would be greater than estimated from this survey. Rice, *et al*, reported that when institutionalized and non-institutionalized elderly are included that diseases of the circulatory system account for 31 percent of the total direct costs.[12] Because the elderly contribute disproportionately to total costs and because chronic disease is responsible for a greater proportion of the cost when institutionalized persons are included, injuries would account for a somewhat lower proportion of medical costs for the elderly.

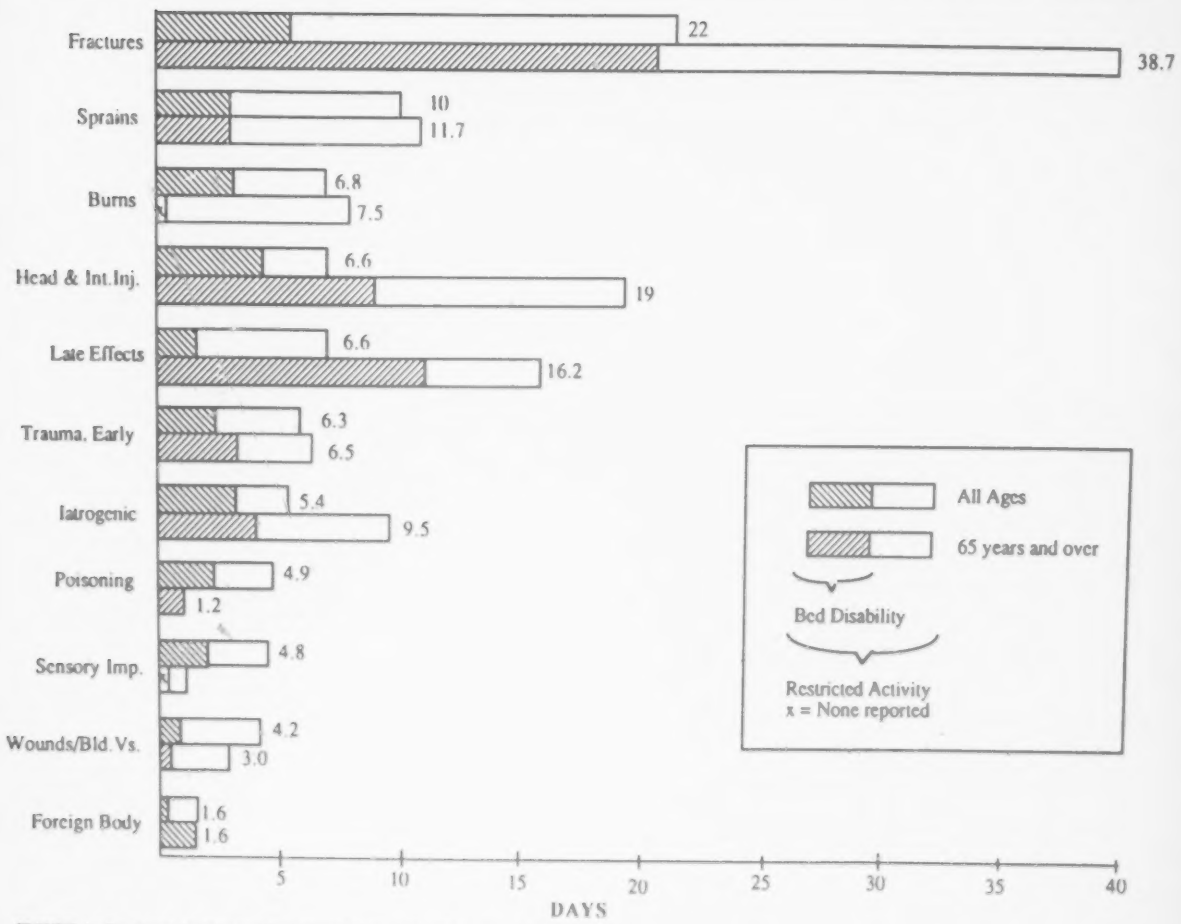

FIGURE 4—Restricted Activity and Bed Disability Days for All Ages and for Age 65+

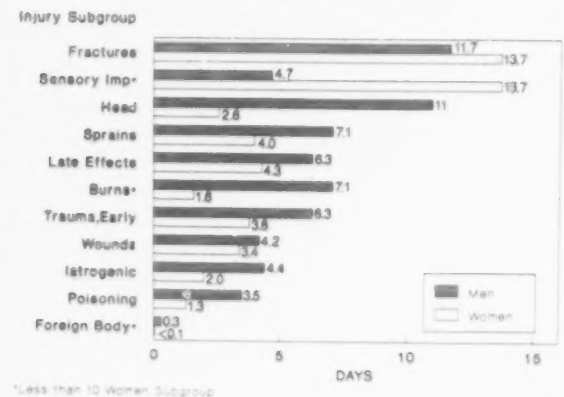

FIGURE 5—Mean Work Loss Days by Injury Subgroup and Gender

The burden of medical costs from injuries are also disproportionately greater for males, persons other than Black, and those with family incomes less than $5,000 (in 1980 dollars). Each of these three groups reports a greater proportion of health care charges attributable to acute injuries and their sequelae than do their counterparts. This maldistribution of costs may reflect differential exposure to potentially injurious situations in the workplace or community. Medical costs for the category of "White and other" might be slightly higher because of the inclusion of "others" in the category. However, the sample weights were computed for "Whites and others" as one category. The "others" category is small and therefore the effect on this category would be minimal.

The economic impact and the demographic pattern of expenditures are concordant with epidemiologic estimates of the health impact of injuries. The potential years of preretirement work life lost as a result of premature mortality from intentional and unintentional injuries was over 4 million years in 1982. This toll was roughly twice the years of potential work life lost from either neoplasms or heart disease.[2] In the National Household Interview Survey of 1980–81, a very high incidence of intentional and unintentional injuries were reported; about 75 million injuries were

reported by 70 million persons.[13] The injury rates were higher for males than for females (40 million versus 30 million), with the greatest number (21 million) occurring in the 17 to 44 year old age group. Both the NHIS and the NMCUES agree on the high occurrence rate in the US population and on the gender and age distributions. These morbidity estimates also correspond to the patterns of national mortality from injuries.[14] Therefore, the mortality, morbidity, and cost data confirm the remarkable impact of injuries.

The economic burden of disease includes the loss of economic productivity to society and income resulting from work loss. These measures of lost productivity were high, reflecting the frequent occurrence of injuries among the younger, working-age population. Injuries accounted for approximately 10 percent of all restricted-activity and bed-disability days during the survey year and about 17 percent of all work-loss days. These estimates exceed the disability and work loss attributable to acute respiratory conditions, which are the most common acute conditions in the general population.[15] These findings agree generally with data from the larger National Health Interview Survey conducted in 1980–81.[13] These findings do not address additional mortality costs to society. Depending on the discount rate used, the mortality costs from injuries are reported to be six to eight times the morbidity costs.[12]

There are considerable social costs in terms of work loss, restricted activity, and bed disability; these costs are distributed across the entire age range. The duration of disability and the mean direct costs are greater for older persons, but the impact of total direct costs and work loss is nevertheless severe for younger adults. MacKenzie, *et al*, examined the functional recovery and medical costs of trauma in patients admitted to two trauma centers and discharged to extended care or rehabilitation facilities or home.[16] Of 262 individuals who were working before their accident, only 57 percent had returned to full-time work within one year.

Examination of total and per capita charges for diagnostic groupings provides further insights into the high costs of injuries. Hospital-based services, including physician fees, dominated the costs for all injury groups. This close linkage of injury care to hospital services indicates that costs for these conditions will parallel the general inflation of hospital operating costs. Because those with the least ability to pay—younger persons and those with low family incomes—have disproportionately higher costs for injuries, it is likely that increasing financial pressures may force many hospitals, and especially those with a large indigent or uninsured clientele, to reassess their ability to provide injury services.[17] A number of hospitals have already terminated emergency care services as a result of cost considerations. In a study of nonaccidental injuries, assaults and suicides, 2,451 patients were admitted to a trauma center.[18] The average charges for the victims of assaults were over $5,000 per patient while the suicide victim's charges were nearly $13,000. Six months after the study had been completed only about 70 percent of the hospital charges had been reimbursed. The authors noted that even if all of the hospital bills were covered the profit margin would only be 1 percent.

The charges associated with specific diagnoses identify conditions and characteristics of persons responsible for generating costs. Fractures accounted for the greatest total direct costs, and per capita costs were also high for this diagnosis. Moreover, fractures were responsible for greater mean disability- and work-loss days than were other diagnoses. Although fractures occurred more frequently in young adults (17 to 44 years), the cost and disability impact was greatest for those over age 65 years. However, fractures occurring in the older population are more likely to result from osteoporosis and hip fractures.[19,20] The diminished resiliency, more frequent requirement for surgical management, and the complicating comorbidity of chronic disease contribute to the greater burden for older persons. For similar reasons, head injuries and late effects of trauma also had a greater effect on older persons. These findings argue that injury research and preventive efforts should not be directed exclusively to the younger adult and employed population, who are generally considered the primary target for these efforts. Prevention and more efficient management of these injuries in the elderly could have considerable economic and health impact.

For conditions other than fractures, the aggregate charges and per capita charges were frequently discordant. For sprains, the per capita charges were relatively low but the high incidence in the population contributed to relatively high total charges. On the other hand, burns occurred less frequently but had higher per capita charges.

The diversity of the conditions included as injuries and the differences among them with respect to per capita costs and disability have implications for public policy. The most effective medical and cost reduction strategy would be prevention. Prevention would affect not only the less common and more expensive conditions but also the total costs of less expensive and commonly occurring conditions by decreasing the incidence of both. Prevention requires specification of the site and circumstances of injury. In NMCUES, there was no inquiry about the causes for the injuries or the sites of occurrence. However, in the contemporaneous National Health Interview Survey, vehicular accidents, industrial accidents, and the home were the most frequent sites of injury.[13] Examining type of accident or manner of injury as the cause of death for 1981, motor vehicle accidents were by far the leading cause of death,[21] followed by falls, fires, and drowning. Major cost containment strategies should be directed toward prevention at all potential sites as well as toward cost efficient urgent and emergency care. These data from NMCUES document the cost of post-emergency care for fractures, trauma, and burns and indicate the potential value of developing more cost-efficient care.

The remarkable impact of injuries raises important public policy issues. Compared with the considerable attention directed toward heart disease, cancer, and recently AIDS (acquired immunodeficiency syndrome), the health professionals and the public appear less concerned with injury research and prevention. The federal research investment in prevention and treatment of injuries was estimated to be $112 million in 1983 or about one-tenth of the research commitment to cancer and one-sixth of that to heart disease and stroke.[1] Moreover, only about one-fourth of federal research investment in injuries was directed toward prevention with the remainder devoted to injury mechanisms, acute care, and rehabilitation.[1] In the context of high medical care costs, this research investment is extremely small. The national costs for injury care exceed those for cancer and are nearly as great as for heart disease. The years of life lost and indirect costs from disability and work loss exceed those for either of these disease categories. The extremely small research commitment to injuries contrasts sharply with the commitment to cancer and heart research. From the perspective of research investment as a proportion of health care

costs, injury had less than 1 percent (actually 0.7 percent) of the care cost invested in research. The comparable proportions for cancer and heart disease were 9 percent and 3 percent, respectively.[1]

Several philosophical, political, and financial reasons can be cited for the public oversight. Importantly, injuries may still be considered to result from random and unalterable events and thus be unpredictable and unpreventable. Even the relatively sparse epidemiologic data from investigation of accidents, injuries, and outcomes indicate that this is not true.[22] Further investigation should improve prediction and afford major decreases in injury rates and injury costs.[23] The lack of research monies probably relates to the absence of a focus for organizing a professional and public constituency. Without a focus of responsibility for defining and reporting injuries, funding research, and monitoring change, there is little political action to reassess priorities and generate new and useful knowledge. From the economic as well as the health perspective, the need warrants greater attention.

APPENDIX
Diagnostic Categories and ICD Codes for Accidents and Injuries

Diagnostic Category	ICD Code
Fractures	800–829
Sprains, strains, dislocations	830–839 840–848
Intracranial, internal injury	850–869, 950–957 special NCHS codes
Open wounds, injury to blood vessels	870–879, 880–887, 890–899, 900–904
Late effects of injuries, poisonings, toxic effects of external cause	905–909
Other early complication of trauma	910–919, 920–924 925–929, 958–959, 990–995
Effects of foreign body entering through orifice	930–939
Burns	940–949
Poisonings, toxic effects	960–979, 980–989
Complications of medical, surgical care	996–999
Partial impairment of senses or other special impairment from accident or injury	special NCHS codes for sensory impairment

Evaluation of Active versus Passive AIDS Surveillance in Oregon

Steven K. Modesitt, RN, MPH, Sharon Hulman, RN, BSN, and David Fleming, MD

Abstract: We searched for unreported AIDS cases in Oregon through death certificate and medical record review, and enhanced infection control practitioner and physician surveillance. Fifty-six AIDS cases diagnosed between February 1, 1986 and January 31, 1987 were reported passively. Twenty-nine additional cases diagnosed during this time were retrospectively identified by active methods. Ninety percent of those 29 cases were diagnosed by physicians and cared for in hospitals that had previously reported cases. Completeness of reporting under the passive system was 64 percent. (*Am J Public Health* 1990; 80:463–464.)

Introduction

Since the acquired immunodeficiency syndrome (AIDS) was first described in 1981, surveillance for AIDS cases has served to define the modes of transmission and to characterize the populations most affected. To date, there have been little data to assess the need for these active surveillance systems, that seek AIDS case reports through a variety of methods rather than passively depending on physician reporting. This study assesses the need for active AIDS surveillance systems. The HIV (human immunodeficiency virus) program of the Oregon Health Division initiated prospective active surveillance for AIDS in February 1987. We applied the methods used for active surveillance to retrospectively determine the number and characteristics of AIDS cases that had gone unreported under the previous passive system. We report here the results of that evaluation.

Methods

We used four active surveillance methods to identify unreported cases diagnosed between February 1, 1986 to January 31, 1987, the year before active surveillance began.

- All physicians in Oregon were sent a letter reviewing AIDS reporting requirements and soliciting case reports. Physicians who had previously reported at least one AIDS case were provided with a list of all these cases for review and asked to report additional unreported cases under their care.
- Infection control practitioners at hospitals where previous AIDS cases had been diagnosed were asked to compile a list of previous AIDS admissions and maintain a log of subsequent admissions for comparison with our central AIDS registry. Those from hospitals without reported cases were asked every six months to confirm that no AIDS-related admissions had occurred.
- At all hospitals statewide where at least one case had been diagnosed, medical records of all potential AIDS admissions were reviewed. Admissions were pulled if they contained any of five International Classification of Diseases, Volume 9 (ICD-9) codes (042, 043, 279.19, 136.3, 173.9) previously shown to be reliable in identifying persons with an AIDS diagnosis.[1] Cases were matched with reported cases in the central registry and physicians of possible unreported cases were queried.
- Death certificates designating AIDS or listing a cause of death potentially AIDS-related (including all deaths related to known opportunistic conditions and deaths from infectious or immunosuppressive causes in persons under age 60) were reviewed. Physicians of potential unreported cases were queried.

A case diagnosed during the year before active surveillance began was considered to be discovered by **active surveillance** if it was reported by any reporting source after the start of active surveillance and more than 6 months after diagnosis. All other cases were classified as reported by passive surveillance. All cases met the 1985 CDC surveillance case definition.[2]

Results

Completeness of Reporting

Fifty-six AIDS cases diagnosed between February 1, 1986 and January 31, 1987 were reported under the passive system. Using active surveillance methods an additional 29 cases diagnosed during this time were found retrospectively. The completeness of reporting before active surveillance began was 64 percent (95% confidence interval = 54, 74). For cases reported under the passive system, the median time between diagnosis and report, or lag time, was one month. Lag time ranged from 7 to 19 months for cases found by active surveillance only (median = eight months).

Characteristics of Cases and Reporting Sources

Cases reported by passive surveillance did not significantly differ from those identified by active surveillance by age, race, county of residence, risk factors, disease at diagnosis or mortality status at time of report, although our power to detect significant differences was limited by the relatively small sample size (Table 1).

Characteristics of physicians who reported cases by passive surveillance did not differ from physicians whose cases were identified under active surveillance by specialty,

Unknown	1	1.8	0	0

city of practice, or previous reporting history. Ninety percent (26/29) of cases identified by active surveillance were cared for by physicians who had reported at least one case before the start of active surveillance.

Characteristics of hospitals from which cases were reported passively did not differ from hospitals where cases were identified under active surveillance by previous reporting history, bed size, or location. Ninety percent (26/29) of cases identified by active surveillance were diagnosed in hospitals that had cared for at least one case before the start of active surveillance.

Efficacy of Active Surveillance Components

We compared the relative effectiveness of each component of active surveillance in identifying previously unreported cases. The initial reporting source for cases identified actively was physicians for 14 percent, infection control practitioners 31 percent, medical record review 31 percent, and death certificate review 24 percent. We estimated the completeness of the surveillance system using the capture-recapture methodology (Chandra Sekar and Deming method).[3] Our surveillance system was divided into two independent reporting components: unsolicited (physician or infection control practitioner reporting) and solicited (medical record review or death certificate review). The percentage of cases found by unsolicited means was 80 percent. The percentage of solicited reports was 95 percent. Seventy-seven percent of cases were found by both methods. The estimated completeness of reporting was 99 percent of the estimated case population.

Discussion

Relative to active AIDS surveillance, the completeness of passive AIDS surveillance in Oregon in 1986–87 was only 64 percent, similar to preliminary findings from South Carolina[4] and less than an earlier New York study.[5] Passive AIDS surveillance, even in relatively low incidence areas, is incomplete. Projections based on passive surveillance would underestimate future incidence proportionately and could result in poor public health planning and resource distribution decisions.

Because almost all cases during this time in Oregon were occurring in urban gay and bisexual men, we recognized at the outset that we would not be able to assess differences in reporting based on case risk factor.

Infection control practitioners, medical record review, and death certificate review were all useful in identifying cases unreported more than 90 days after diagnosis. Each of the multiple reporting components independently identified cases that would otherwise have gone unreported.

Physicians and hospitals with previous reporting history appear to be the reservoir for the largest number of unreported cases and are the best targets for enhanced surveillance activities. As the epidemic continues, the ability to maintain effective active surveillance will include using resources efficiently, combating "reporting fatigue," and assuring timely reporting as clinical practice shifts diagnosis to outpatient settings. As the AIDS epidemic progresses and physicians and hospitals gain more experience with this disease, active surveillance may become more rather than less important.

The Prevalence of High-Risk Sexual Behavior in Male Intravenous Drug Users with Steady Female Partners

Diane K. Lewis, PhD, MPH, John K. Watters, PhD, and Patricia Case, BA

Abstract: A sample of 149 (70 White, 79 Black) male intravenous drug users with steady female sexual partners was interviewed in 1987, in treatment and street settings, about sexual practices during the previous five years. Eighty-three percent had multiple partners, 15 percent reported male sexual contact, 38 percent reported heterosexual anal intercourse, and 73 percent never used condoms. Thirty-seven White and 30 Black subjects reported bisexuality or heterosexual anal intercourse or both. (*Am J Public Health* 1990; 80:465–466.)

Introduction

Research on AIDS (acquired immunodeficiency syndrome) prevention among intravenous (IV) drug users has focused primarily on needle sharing,[1,2] with few studies to date on high-risk sexual behavior.[1,3] Since sexual behavior may prove more difficult to change than needle behavior,[2,4,*] more information is needed to design effective AIDS education programs. This paper presents the prevalence of high-risk sexual behavior in a sample of male IV drug users in San Francisco.

Methods

Data on sexual behavior were collected in early 1987 from 149 male IV drug users with stable female sexual partners. The men were a sub-set of a larger study of risk behaviors for human immunodeficiency virus (HIV) transmission among 632 male and female IV drug users. Of the 411 male subjects, 34 had exclusively male sexual contacts during the previous five years and 377 had sexual contact with females during that period. Of these 377, 134 were White, 171 were Black, and 82 were Hispanic or other ethnic backgrounds. Participants were asked: "Do you have a steady sexual partner (or partners)?" If they answered yes, they were asked whether the partner(s) was male, female, or both. Of the 377 males, 201 reported a steady partner or partners; 184 had a steady female partner, 14 had a steady male partner, and three had both a male and a female partner. One White and one Black male reported both a female and a male as steady partners. Information on length of relationship was not obtained. Men with no steady sexual partners, those whose partners were exclusively male, and those of Hispanic or other ethnic backgrounds were not included in this study.

Subjects were recruited from a 21-day methadone clinic and a symptomatic (nonmethadone) clinic, and from three street settings. In-treatment subjects had a documented history of opiate addiction (the methadone clinic), or were identified by staff as having injected drugs during the three weeks prior to admission (the symptomatic clinic). Of those contacted in the two clinics, 86 percent agreed to participate. Out-of-treatment subjects, recruited via word of mouth through a targeted sampling technique,[5] reported needle use within three weeks of interview and showed signs of recent venipuncture. The refusal rate for street subjects is unknown because of the chain-referral recruitment method.

Structured 45 minute interviews were conducted by trained interviewers who questioned subjects about demographic characteristics, medical history, drug use patterns, and AIDS awareness, as well as sexual behavior. Subjects were asked their total number of female sexual partners during the previous five years; if they had sexual contact with males; if they ever engaged in heterosexual anal intercourse, and the percent of time of condom use.

Results

Of the 149 subjects, 70 were White and 79 were Black; less than one-fifth (18 percent) of the subjects were currently married. Age ranged from 20 to 66 years; the median age of Whites was 33.5 years, of Blacks 36 years. Eighty-eight (59 percent) of the men were interviewed out-of-treatment, 27 (39 percent) of the White subjects and 61 (77 percent) of the Black subjects.

High Risk Sexual Activities

Over four-fifths (83 percent) of the men reported more than one female sexual partner during the previous five years, 60 percent had five or more, and 39 percent had 10 or more. Whites had a median of 7.5 partners and Blacks a median of five partners.

Twenty-two (15 percent) of the 149 men reported sexual contact with a male (13 percent of the Whites and 17 percent of the Blacks). White subjects who reported same-sex activity had a median of 20 female partners and three male partners. Black subjects who reported bisexual activity had a median of 10 female and three male partners.

Heterosexual anal intercourse was reported by 56 (38 percent) of the men (46 percent of the Whites and 30 percent of the Blacks). Almost three-fourths (73 percent) of the men said they never used condoms.

Table 1 shows the distribution of subjects engaged in high-risk sex by treatment status and by ethnicity. Twenty-seven of 61 in-treatment subjects and 29 of 88 out-of-treatment subjects reported either bisexuality or heterosexual anal intercourse. In all, 33 White and 23 Black subjects reported either male sexual contact or heterosexual anal intercourse; seven Black and four White subjects engaged in both activities (see Table 1).

The majority of men engaged in high-risk sex reported non-use of condoms (Table 1). Fourteen of 22 men who had male sexual contact, and 41 of 56 men who engaged in

*One subject with a missing answer.

heterosexual anal intercourse said they never used condoms (data not shown).

Discussion

Overwhelmingly research on IV drug users is conducted in treatment programs.[5,6] In this study, the majority of subjects were recruited out-of-treatment. Because this was not a random sample, the results may not be generalizable. Other limitations are a lack of information on duration of partner relationships and the problem of bias in recalling and accurately portraying past sexual activity.

Due to a lack of comparable studies, it is unknown whether the range and level of sexual activity reported by these subjects is similar to other IV drug users. The sexual risk taking in this sample may be connected with recent increases in cocaine injection and smoking.[7,8] Because cocaine has been linked with heightened sexual activity in some studies,[9,10] the impact of it and other drugs on high-risk sexual behavior merits study.

The numerous sexual partners and the high-risk practices reported by a majority of these IV drug users indicate the potential for widespread secondary transmission of HIV. The difficulty in reducing sexual risk behavior is shown by the high proportion of subjects in this study who reported non-use of condoms, despite out-reach risk reduction programs, initiated in 1986, which included widespread distribution of free condoms to IV drug users in San Francisco.[4,**]

Further research is required on ways to overcome barriers to condom use and to reach heterosexually identified male IV drug users engaged in sexual activity with males. Continued aggressive culturally sensitive out-reach sexual risk reduction strategies are needed, since many IV drug users may not be enrolled in treatment programs.[11–13]

Are Patients Talking to Their Physicians about AIDS?

BARBARA GERBERT, PHD, BRYAN T. MAGUIRE, BSC, AND THOMAS J. COATES, PHD

Abstract: We conducted a nationwide telephone survey of a random sample of United States adults in summer 1988 (n = 2000, response rate = 75 percent) to find out if physicians were providing education and counseling to the public about AIDS and AIDS prevention. Within the previous five years, 94 percent had seen a physician but only 15 percent had discussed AIDS even though most said they would not object to discussing the topic. AIDS-related conversations are not commonplace in physician's offices and in most cases (72 percent) patients are the initiators of such conversations. (*Am J Public Health* 1990; 80:467–468.)

Introduction

Physicians have been encouraged to discuss AIDS (acquired immunodeficiency syndrome) risk reduction with all of their patients and to take sexual histories to help all patients identify and modify risky behavior;[1,2] physicians are well placed to provide this service, as approximately 76 percent of Americans see a physician annually.[3] Moreover, 60 percent of respondents to a National Center for Health Statistics survey[4] said that they would ask a physician if they wanted specific information about AIDS.

Methods

Telephone interviews were completed with a representative sample of 2000 civilian, non-institutionalized United States adults (75 percent response rate) between July 5 and August 19, 1988. In selecting the sample, the country was divided into two strata by AIDS prevalence and subjects were drawn using a random-digit-dial procedure. There were 1000 respondents from each stratum.

The data reported here are based on weighted estimates for the two strata combined. Given the stratification design effect (the ratio of the variance of design used to that of a simple random sample of the same size), the effective sample size for population estimates was 1320.[5] The confidence intervals in Table 1 reflect this design effect.

Subjects were selected randomly within households. To partially correct for known biases in the selection of respondents resulting from random digit dialing,[6] responses were weighted by the number of persons in the household and the inverse of the number of telephone lines in the household. To correct for small differences between the demographic characteristics of the sample and census estimates, data were also weighted by race, sex, and age.

The interview contained 70 items concerning public perceptions about AIDS and health care. Items about physician counseling are presented in the Appendix. Ninety-four percent of respondents recalled seeing a physician at least once in the past five years; 76 percent of respondents had visited a physician in the past year. Data reported here are from respondents who had seen a physician in the past five years, referred to later in this paper as "patients." Further details of the methods have been reported in earlier papers.[7–9]

Results

Only 15 percent of patients recalled ever talking to their physicians about AIDS. The demographic groups more likely to have discussed AIDS were young people, Blacks, people with a high household income, or people who lived in an SMSA with high AIDS prevalence (Table 1). In addition, those for whom AIDS was personally most salient, for example those who knew someone with AIDS or HIV (human immunodeficiency virus) infection, were more likely to have talked to their physician about the disease (Table 1). Of the 240 patients who had talked to their physician about AIDS, physicians initiated the conversations in only 28 percent of the cases.

Patients had discussed a variety of AIDS-related issues with their physicians; sexual behavior and safe sex were discussed most frequently. Risk of transmission from blood transfusions

and other health care-related risks were also discussed frequently, as were concerns about casual transmission.

Among patients who had not yet spoken with their physician about AIDS, 56 percent did not express a preference for or against talking to their doctor about AIDS, only 17 percent said they would not want to discuss the topic with their doctor, and 27 percent wanted to do so. Younger respondents (32 percent) and Blacks (37 percent) were more likely to want to talk to their physician about AIDS.

Since many AIDS-related concerns have to do with sex, patient-physician interaction regarding sexuality may influence the frequency of discussions regarding AIDS. Most patients (78 percent) did not recall having been asked questions about their sexual behavior at their physician's offices. Only 7 percent of respondents reported they would be unwilling to answer a physician's questions about their sexual behavior; 59 percent said they would be glad for the opportunity to talk to their physician about sex. Most patients (67 percent) said they would be very comfortable talking with their physician about AIDS.

The AIDS-related topics which patients said they would like to discuss are listed in Table 2. Transmission of AIDS, especially by casual contact and in medical settings, heads the list. Although 59 percent of patients said that they would go to their physician or HMO (health maintenance organization) for more specific information on AIDS, respondents reported getting most of their information from television (mentioned by 67 percent), newspapers (56 percent), and magazines (36 percent).

Discussion

Relatively few patients had discussed AIDS with their physician. This is consistent with previous reports based on physician surveys[10] and more limited patient surveys.[11] Previous studies[12] have also documented the infrequency of sexual history taking. It should be noted, however, that the denominator for the history taking and AIDS counseling items includes all patients who have had any physician contact over the past five years. Many of these contacts may not have been appropriate situations for these preventive practices. Although fallibility of patient recall may also lead patients to underestimate counseling by physicians, if patients do not remember having discussed AIDS, it is unlikely that the counseling was effective. Although the methodology of this survey may yield conservative estimates of physicians' actual counseling efforts, the evidence remains that AIDS-related discussions are not commonplace in physicians' offices.

TABLE 2—AIDS Topics People Wanted to Discuss with Their Physician according to the 419 Patient-respondents (27%) Who Said They Wanted to Talk to Their Physician about AIDS but Had Not Yet Done so

Topics for Discussion	%
AIDS transmission—general information	23.9
Risk from casual contact	21.0
Contagion in medical settings	11.7
Sexual behavior, safe sex	9.5
Prevention/avoid contracting AIDS	7.9
Treatment for AIDS	7.6

APPENDIX

Survey Items Concerning Patients' Experience and Opinions about AIDS Education by Physicians

- Have you ever talked to your medical doctor about AIDS?
- Who started the conversation . . . you or the doctor?
- What was it about AIDS that you and your doctor discussed? *(open-ended)*
- Would you want to talk to your doctor about AIDS, would you prefer not to discuss this with your doctor, or do you not care?
- What is it about AIDS that you would like to discuss with your doctor? *(open-ended)*
- If you were to talk with your doctor about AIDS, should they start the conversation, or would you rather start it yourself?
- Have you ever been asked questions at the doctor's office about your sexual behavior?
- It has been suggested that medical doctors should ask their patients about their sexual behavior as part of a routine health history taking. If your doctor asked you about *your* sexual behavior, would you be glad for the opportunity to share this information with your doctor, be somewhat uncomfortable but answer the questions anyway, or would you be unwilling to talk about these matters with your doctor?
- How comfortable would you feel . . . *(insert a through c)* . . . very comfortable, mostly comfortable, somewhat uncomfortable, or very uncomfortable?
  a. if you had a conversation with your doctor about AIDS
  b. if your doctor asked you questions about your sexual behavior
  c. if your doctor asked you questions about your use of intravenous drugs
- According to medical authorities, the following groups of adults are at highest risk for AIDS: people who received blood transfusions between 1977 and 1985, intravenous drug users, men who have sex with other men, and anyone who has had many sex partners. Do you know anyone that might be a member of these groups?
- Have you ever personally known anyone with AIDS or the AIDS virus?

Screening for Chlamydial Cervicitis in a Sexually Active University Population

C. Kevin Malotte, DrPH, Edward Wiesmeier, MD, and Kristin J. Gelineau, RN, NP, MN

Abstract: Enzyme-linked immunoabsorbent assays to detect chlamydial cervicitis were performed on samples from 1,320 sexually active university women. Seventy-five (prevalence 5.7 percent) had positive tests. Demographic, history, symptom, and physical examination variables were insufficient to predict infection accurately. We conclude that screening during routine visits with this population is cost-effective. (*Am J Public Health* 1990; 80:469–471.)

Introduction

Chlamydia trachomatis is the most prevalent sexually transmitted disease in the United States.[1] Until recently, diagnosis of chlamydial infection was handicapped by the lack of an inexpensive diagnostic test. *Chlamydia* is easily treated with antibiotics, but left untreated can persist for an indefinite time, and result in severe sequelae. While symptomatic women have a higher prevalence rate, most women with cervical infections have few or no symptoms.[2]

Methods

Routine screening for chlamydial infection of all sexually active students receiving physical examinations at the University of California-Los Angeles, Student Health Service Women's Clinic was implemented in June 1986. Some women were seen for initial or yearly examinations (routine visit group) and some women were seen for symptoms, partner symptoms, or previous problem follow-up (symptom/problem group).

Specimens were tested using Chlamydiazyme™ kits run according to the manufacturer's directions. Women with positive tests were typically tested with doxycycline 100 milligrams twice daily for seven days. Sexual abstinence was encouraged during treatment; partners were referred for treatment. Test of cure using culture was requested approximately three weeks after treatment.

A total of 1,320 women were screened between June 24 and October 24, 1986. Data were abstracted from the medical records of all but 19 of these women. Data collected included: age, marital status, race/ethnicity, reason for the visit, gynecologic history, present contraceptive use and level of current sexual activity, current symptoms, partner symptoms, physical findings, test results, and clinician diagnosis.

Chlamydiazyme test result was cross tabulated with these variables; prevalence odds ratios (POR) with 95% confidence intervals (CI) were calculated. All variables found to have POR with a lower limit on the 95% CI greater than one were subsequently used in a logistic regression (BMDPLR).[3]

Results

Of the 1,320 women tested, 75 (5.7 percent) had positive Chlamydiazyme tests. Thirty-six (5.0 percent) of the 724 routine visit group women had positive Chlamydiazyme tests while 39 (6.8 percent) of the 577 symptom/problem group women had positive tests.

Seventy-four of the 75 women with positive tests at their first study period visit returned for treatment; 65 of the 74 treated women returned for a culture test of cure. All 65 were successfully treated.

Table 1 lists those variables which were related to Chlamydiazyme result for the total sample. In the logistic regression, only five of the 13 variables were independently related to a positive test.

Recognizing that a logistic regression equation is likely to be too complicated for most clinicians to apply, a risk-factor index similar to those used by others[4,5] was constructed by summing presence of positive findings on each of the five independently related variables. Thus, women with none of the findings were assigned a score of 0, and women with all five of the findings were assigned a score of five. Table 2 lists sensitivity, specificity, and predictive values using different scores on the index as cutpoints.

Parallel analyses to those conducted for the total sample were conducted separately for women who were seen for routine visits, and those who were seen for problem/symptom visits. Results were not substantially different, but are available upon request

Discussion

Prevalence rates of chlamydial infection among female college students have ranged between less than 5 percent to nearly 10 percent.[6–14] The 5.7 percent prevalence of cervical infection we observed is at the low end of this range. However, our prevalence among women age 22 years and younger in our study was 8.7 percent; the relatively large number of older students in our study may account for the lower rate.

The literature is divided over whether medical history and examination are adequate to identify infection.[12,14] In our study, if only women who had one or more of the risk factors found to be independently related to a positive test had been screened, 694 women would not have been screened at a significant savings in resources, and 81 percent of the women

**Variables independently related to Chlamydiazyme result in logistic regression

with a positive test would have been tested. However, 14 (19 percent) of the 75 women with positive tests would have been missed. In our sample, 27 (36 percent) of the 75 women with positive tests had entirely normal physical examinations. Thus it appears while signs, symptoms, history, and demographic variables would be helpful in determining whether to test for infection when laboratory resources are limited, these variables are insufficient to predict infection *accurately*.

Seven guidelines for determining whether a screening program is likely to be effective have been proposed.[15] If a randomized clinical trial has shown the effectiveness of a screening program, the assessment is relatively easy. We are unaware of any randomized trials of screening for chlamydial infection. However, we believe a screening program in our female population satisfactorily satisfies the other six guidelines.

For example, several tests are available which could be used to screen for *chlamydia*. We chose to use Chlamydiazyme, which has compared favorably with culture in our population.[10] The importance of the screening test and the prevalence of the condition is especially important when considering possible negative effects of a screening program. Using the specificity (99.5 percent) and prevalence (4.9 percent) found in our previous studies,[10] less than one out of 10 women who are told they are infected will be erroneously told so.

The costs of alternative strategies for screening during routine gynecologic visits were recently analyzed.[16] A strategy using no screening was compared with a strategy involving the routine use of culture, and a strategy using a less costly but less sensitive and specific alternative test. The analysis indicated that the alternative test would need to cost about $10 per test at a prevalence of 5 percent for the screening strategy to be cost effective. Because our screening test is both more sensitive and specific than the estimates used in that analysis, and our cost per test is less than $8, it appears that screening among our population can be supported on economic as well as clinical grounds.

Prevalence of Markers for Hepatitis B and Hepatitis D in a Municipal House of Correction

M. Anita Barry, MD, MPH, Donna Gleavy, RN, Kay Herd, RN, MPH, Pamela J. Schwingl, MS, MA, and Barbara G. Werner, PhD

Abstract: Following an outbreak of hepatitis B (HBV) in a municipal house of correction, HBV markers were detected in 173/406 (43 percent) inmates and 10/129 (8 percent) staff. Of the 173 HBV-infected inmates, 14 (8 percent) had hepatitis D (HDV) markers compared to 0/10 staff members. Intravenous drugs use (IVDU) was most strongly associated with HBV marker presence. Increasing duration of imprisonment, history of hepatitis B and especially IVDU were associated with the prevalence of HDV markers. (*Am J Public Health* 1990; 80:471–473.)

Introduction

Hepatitis D (HDV) is caused by an incomplete RNA virus dependent on hepatitis B virus (HBV) for survival.[1,2] Estimates of its prevalence range from 0–10 percent in chronic HBV carriers to 30–50 percent in persons with fulminant hepatitis B.[3] Most data suggest that in the United States intravenous drug users and hemophiliacs are at increased risk for HDV.[4] Although higher prevalence of HBV markers in prisoners or inmates of correctional facilities when compared to the general population has been described in several studies, similar data on HDV in incarcerated populations are not available.[5–10]

In January 1985, the Boston Department of Health and Hospitals was notified that five inmates in the Suffolk County House of Correction had an acute onset of hepatitis B. One inmate was coinfected with HDV and died of fulminant hepatitis. All inmates and employees were offered HBV screening and subsequent vaccination if seronegative as part of an outbreak control plan. While providing epidemiological assistance, we had the opportunity to evaluate the HDV status in those with HBV markers.

Methods

The Suffolk County (Massachusetts) House of Correction at Deer Island, operated by the City of Boston Penal Institution Department, accommodates 460–480 inmates, who serve an average sentence of 11 months. There are approximately 210 staff members employed at the facility including two registered nurses and one part time physician who staff an on-site infirmary.

In February 1985, a fact sheet on HBV and HDV was distributed to all inmates and staff, and participation in an HBV screening and vaccination program was solicited. Participants were questioned by one of the investigators regarding age, duration of involvement with the prison system, history of prior hepatitis, history of intravenous drug use (IVDU), location within the prison facility, and primary city of residence.

Serum was obtained to determine presence of HBV core antibody (anti-HBc; CORAB, Abbott Laboratories, N. Chicago, Illinois). Sera with borderline anti-HBc results were also tested for hepatitis B surface antigen (HBsAg) and antibody (anti-HBs) (AUSRIA and AUSAB, respectively, Abbott Laboratories). All anti-HBc positive specimens were also analyzed for HDV antibody (anti-delta; Abbott Laboratories). An interpretation of test results was given to each participant and HBV vaccination offered to those without HBV markers. This protocol was approved by the Boston Department of Health and Hospitals Institutional Review Board.

The magnitude of relative effect was assessed for several risk factors of HBV positivity. Univariate and multivariate

TABLE 1—Characteristics of Participants in a Hepatitis Screening Program in Prison, Boston, 1985

Characteristics	Inmates (N = 406) (%)	Employees (N = 129) (%)
Mean age (years)	27.8	33.9
Mean duration of prison involvement (years)	2.2	5.7
History of hepatitis, any type	45 (11)	5 (4)
History of hepatitis B	17 (4)	0 (0)
History of homosexual activity	12 (3)	0 (0)
Intravenous drug use	136 (33)	2 (2)
Anti-HBc positive	173 (43)	10 (8)

analyses were conducted using SAS procedures to calculate odds ratios, test-based confidence intervals,[11] and logistic regression coefficients. Crude odds ratios (OR) and their exact 95% confidence intervals (CI) for risk factors in the 14 cases of HDV were calculated using the method described by Gart.[12]

Results

Of 463 inmates offered screening, 409 (88 percent) agreed to participate. Of these 409, three had equivocal anti-HBc results and are not included in further analysis. Characteristics of participants are shown in Table 1. There was no discernible pattern in findings related to city of residence.

Of the 142 employees invited to participate, 129 (91 percent) agreed. Their characteristics are shown in Table 1.

By univariate analysis, risk factors for HBV among prisoners included age greater than 30 years, prior history of HBV, and IVDU. In the multivariate model prior history of hepatitis was also included. Tests for interaction of age and IVDU and for other potential interactions were not significant. By multivariate analysis, IVDU was most strongly associated with HBV marker presence (OR = 6.0, 95% CI = 3.6, 10.2). Increasing duration of incarceration, independent of age or IVDU, was also related to the presence of HBV markers (Table 2).

Of the 173 specimens from inmates with anti-HBc, 14 (8 percent of all inmates) contained anti-delta. Relative odds of IVDU, imprisonment for one to four years and for five years or more, history of hepatitis B, and age over 30 were elevated. All prisoners positive for HDV reported that they had had some type of hepatitis in the past, and 12 of the 14 reported both a history of hepatitis and IVDU. The small numbers and correspondingly wide intervals, and the inability to control joint confounding in this data set, prevents further interpretation of the data.

Discussion

Several studies have documented a high prevalence of HBV markers in prison populations.[5–10] Reported figures are comparable to the proportion reported here of 43 percent. As in other studies, IVDU was found to be strongly associated with evidence of HBV infection. One-third of our inmate participants gave a history of intravenous drug use. This figure may not be reflective of correctional institutions as a whole, and thus the prevalence of HBV markers may differ in other facilities.

Less information is available on the prevalence of HDV infection in inmates of correctional facilities. A previous study revealed that four of 19 prisoners (21.1 percent) known

to be infected with HBV in a county jail had markers for HDV, two with antigen and two with antibody.[4] In the current study all participants were healthy at the time of screening, and the anti-delta positive results presumably represent past infection. Although one of the five cases of HBV in the outbreak that precipitated the screening/vaccination program contained IgM anti-delta, specimens from persons in this program were not evaluated for the presence of HDV antigen or IgM anti-delta. Thus some acute HDV infections could have been missed. The proportion of specimens containing anti-delta (14/173, 8 percent) from inmates in this study, however, approximates the proportion of HDV antibody noted in inmates by the study by Jacobson, *et al.*[4] As with HBV, IVDU was strongly associated with the presence of anti-delta; of the 14 inmates with markers for HDV, 12 (86 percent) gave a history of IVDU. Ponzetto, *et al.* previously reported that 10 percent of drug addicts participating in a Veterans Administration (VA) cooperative study had evidence of infection with HDV.[13]

Measures that protect against HBV infection, such as use of hepatitis B vaccine, are also effective in preventing HDV infection. Implementation of HBV preventive guidelines in corrections facilities should reduce the risk of HDV.

Influenza Epidemics and Anencephaly

LAURI SAXÉN, MD, PHD, PETER C. HOLMBERG, MD, PHD, KARI KURPPA, MD, PHD, EEVA KUOSMA, MSC, AND REIJO PYHÄLÄ, PHD

Abstract: To explore the postulated association between maternal influenza and congenital defects of the central nervous system, 14 virologically verified epidemics in Finland, 1969–82, were studied. Mothers of 248 anencephalic children were grouped into those whose first trimester had occurred during an epidemic period and those whose pregnancy had commenced during a non-epidemic period. No significant differences in prevalence of anencephaly were noted in these groups. (*Am J Public Health* 1990; 80:473–475.)

Introduction

There is ample evidence that certain virus infections can be transmitted to the embryo during pregnancy and cause impaired fetal development expressed as congenital defects.[1] Among these potential teratogens, influenza virus has been frequently mentioned, but evidence for or against such harmful effects has remained inconclusive.[2,3] We have conducted a population study based on recorded influenza epidemics and one particular marker defect, anencephaly. This defect has several advantages for investigative purposes: its detection rate is high in stillbirths and in newborn infants, the diagnostic means have not changed during our 15-year-study period, notification rate of this severe defect is high, and finally, as it is a lethal condition, the reports to the Register of Congenital Malformations can be confirmed and completed from the compulsory death certificates. Moreover, defects of the central nervous system (CNS) have often been mentioned in the context of maternal influenza.[2–6]

Methods

The material was collected from the files of the Finnish Register of Congenital Malformations operating since 1963[7,8] and completed with data from the death certificates obtained from the Central Statistical Bureau. These sources cover the entire population of 4.9 million; the present analysis includes all mothers whose last menstruation occurred between October 1, 1968 and March 31, 1982, comprising 858,917 deliveries. Altogether 248 cases of anencephaly were recorded in children weighing 600 g or over at birth. Of these, 201 cases were single defects and, in 47, additional malformations were reported.

Influenza activity in the Finnish population has been monitored by the Central Public Health Laboratory since 1969 with virus isolation and serodiagnostics of acute respiratory infections. Our study covered 14 epidemic periods during which influenza etiology was confirmed. Excluding sporadic cases and small local outbreaks, the epidemic time

(a) The pairs consisted of pre-epidemic and postepidemic specimens.
(b) Epidemic activity recorded, but infection frequency among pregnant women not studied.

was 37 months of the total 162 months monitored during the study period. To create a "non-epidemic" control material, the month preceding and following each epidemic was excluded because of timing uncertainties. Altogether, 26 such borderline months with 46 anencephalic children were thus excluded.

Since the end of 1971, the influenza surveillance program has included annual monitoring of serological infection frequencies among pregnant women in Finland.[9] Serum pairs of pre-epidemic and post-epidemic specimens from a total of 4,252 women were studied for haemagglutination-inhibiting antibodies to influenza A and B viruses including the epidemic variant, and, for detection of anamnestic antibody response, the serotypes of the near past (Table 1). A fourfold or higher rise in antibody titers was considered indicative of serological influenza infection.[9]

For the occurrence of anencephaly in infants, mothers whose first trimester (14 weeks from the start of the mother's previous menstruation) had coincided wholly or in part with a virologically verified influenza epidemic (407,200 mothers) and mothers whose first trimester had occurred completely during a non-epidemic period (314,841 mothers) were compared after exclusion of the borderline months. Power calculations were performed according to Schlesselman.[10] The heterogeneity test was performed and confidence limits for rate ratio estimates were calculated as suggested by Miettinen.[11] Trend analysis for the proportion of rates of anencephaly was performed according to Armitage.[12]

Results

Epidemics caused by influenza A and B viruses, and serological infection frequencies in the follow-up samples of pregnant women are listed in Table 1. Figure 1 shows the rates of anencephaly when the first trimester had occurred during the influenza epidemics or during the non-epidemic periods. In the epidemic group, 117 anencephalics were reported and in the non-epidemic group, 85; prevalence 0.29 per mil and 0.27 per mil, respectively.

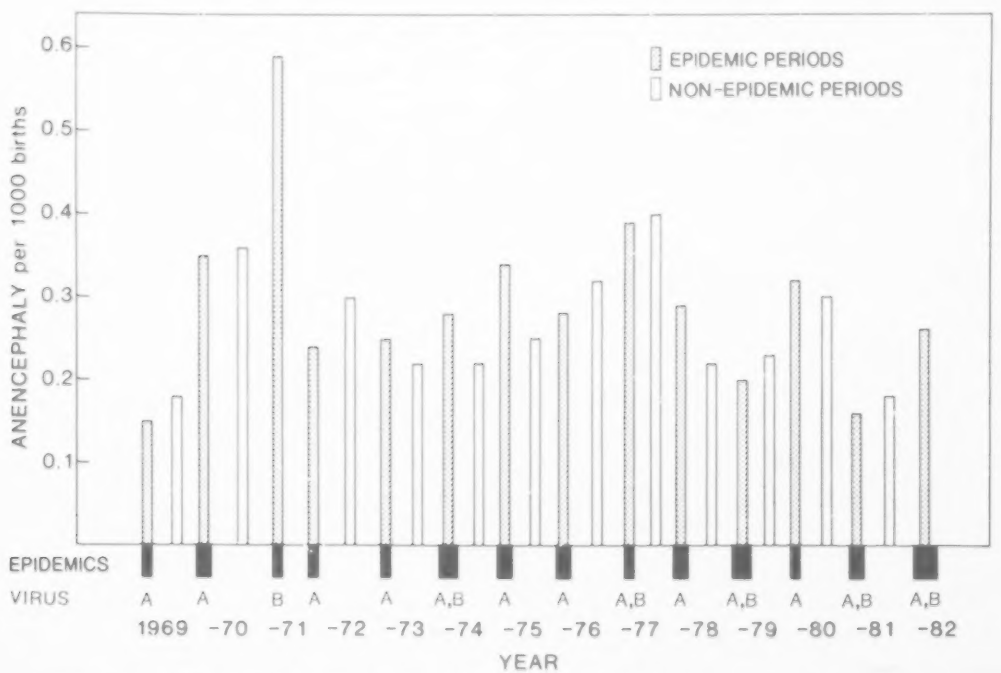

FIGURE 1—Prevalence of Anencephaly in Children Whose first 12 Weeks of Development Coincided either with an Influenza Epidemic or with the Non-Epidemic Periods

When the rates of anencephaly were examined in relation to the serologically verified influenza epidemics, the April-May 1971 B-influenza epidemic showed an apparently high rate in comparison with other periods (Figure 1). However, the heterogeneity test indicated that within the study period of 1969–82, none of the observed rates showed statistically significant elevation ($p = 0.75$). It was evident that influenza epidemics in general were not associated with the occurring of anencephaly. The rate ratio point estimate for anencephaly was 1.0 (95% confidence limits 0.8, 1.3), when the infants of mothers whose first trimester had coincided with an influenza epidemic were compared with the infants whose sensitive period of development had occurred during a non-epidemic period. Trend analysis showed no change in the rate of anencephaly for the period of 1969–82 (regression slope −0.0000028, SE 0.0000026).

Discussion

Two previous studies in the same population suggest, as we do here, that an influenza virus infection of the mother might not be a major cause of neural tube defects: serological screening of mothers to defective children showed no elevated titers against influenza virus antibodies as compared with matched-pair controls,[13] and CNS defects showed no seasonal variations in 1965–73 despite the definite winter excess of influenza.[14] The latter finding confirms similar observations in other populations.[15]

An exception to the negative findings listed above seems to be provided by the Asian influenza pandemic in 1957 caused by a new subtype (H2N2) of the influenza A virus. Several independent studies reported an association of this epidemic and an increased risk of defects of the CNS, anencephaly included.[14,16–20] Caused by a new subtype of the virus, the epidemic attacked a highly susceptible population, which might explain the association. In the present material, a similar effect could not be found for the 1968/69 pandemic in which the new subtype H3N2 was involved. The present analysis did not reveal any association between an increased risk of anencephaly and maternal influenza infection. The power of the study was about 80 percent to detect a rate ratio of 1.4 for all epidemics combined and almost 100 percent to detect rate ratios of 1.7 or greater ($\alpha = 0.05$, one-sided).

Rabies Vaccine Adsorbed: Neutralizing Antibody Titers after Three-Dose Pre-exposure Vaccination

BYRON S. BERLIN, MD

Abstract: Field trials at several schools of veterinary medicine showed that three-dose pre-exposure rabies vaccination with Rabies Vaccine Adsorbed developed by the Michigan Department of Health elicited neutralization antibody in practically all recipients two to three weeks after immunization. Titers declined during the first six months after vaccination. However, by 18 to 24 months, 98 percent of recipients still had titers equal or greater than a 1:5 dilution of serum. (*Am J Public Health* 1990; 80:476–478.)

Introduction

Initial clinical trials with Rabies Vaccine Adsorbed (RVA), a new tissue culture derived rabies vaccine developed by the Michigan Department of Public Health,[1] were done with a two-dose pre-exposure immunization schedule.[2] The studies showed that this new vaccine induced satisfactory antibody titers two to three weeks after vaccination and prepared recipients for a vigorous response to booster vaccination. Additional clinical trials, summarized in the present study, were conducted to ascertain antibody responses after administration of this vaccine by pre-exposure immunization schedules recommended by the Immunization Practices Advisory Committee (ACIP), Centers for Disease Control, i.e., three doses of rabies vaccine of tissue culture origin, one dose each day on days 0, 7, and 21 or 28 days.[3]

Methods

Vaccine

The vaccine used in the present study was previously described.[1] Briefly, RVA contains non-infectious, B-propiolactone-treated rabies virus which is adsorbed onto aluminum phosphate. The virus was grown on diploid fetal rhesus monkey lung fibroblasts (FRh1-2), the rhesus analogue of the WI-38 cell. The antigenic potency of each lot of RVA exceeds 2.5 International Units (IU).

Subjects

The study consisted of 24 separate clinical subtrials with a combined enrollment of 1,735 students and staffs from five schools of veterinary medicine: 1,647 with no prior vaccination against rabies and 88 who had not responded to Duck Embryo Rabies Vaccine. The number of volunteers in individual subtrials varied from 16 to 127 and the median size was between 68 and 74 persons. Each person received three intramuscular injections of RVA, 1.0 mL per dose, at 0, 7, and 21 or 28 days and then was bled two weeks after the final dose of vaccine and, depending on the subtrial in which they were included, at six months and nine to 14 months. Volunteers remaining on the campuses were bled 18 to 24 months after vaccination (Table 1). Serum samples were sent to the Michigan Department of Public Health laboratories for antibody determination. Each volunteer provided a brief medical history and signed an informed consent before vaccination.

Serology

Serum neutralization titers were ascertained by the Rapid Fluorescent Focus Inhibition Test (RFFIT)[4] beginning with a 1:5 dilution of the serum and ending with a 1:625 dilution using five-fold dilutions. RFFIT titers, given as International Units (IU), were computed by dividing the reciprocal of the dilution titer of the subject's serum by the reciprocal of the dilution titer of a standard serum, designated as 1.0 IU, tested at the same time. RFFIT titers less than 1:5 dilution of serum, approximately 0.1 IU were considered below the minimally acceptable titer recommended by the ACIP.[3] Titers from 0.2 to 0.5 IU were classed as acceptable because they fell between 0.1 IU and the minimally acceptable initial RFFIT response to post-exposure immunization recommended by the World Health Organization (0.5 IU).[5] Titers above 25 IU were grouped together because the maximum dilution for testing the sera was 1:625.

Results

Ninety-six percent (1,673/1,735) of the vaccinees were bled two weeks after the last dose of the vaccine series (Table 1). Nineteen (1 percent) had either withdrawn voluntarily or were dismissed from the study because of illness or reaction to the vaccine. Forty-three (2 percent) failed to return for bleeding. All but one of the 1,673 who were bled at two weeks had rabies neutralizing antibody titers greater than 0.1 IU.

Subsequently, 91 percent (419/461) of volunteers initially enrolled in five of the 23 subtrials were bled six months after the vaccine series (Table 1) and, of these, 415 (99 percent) had RFFIT titers greater than 0.1 IU. Nine to 14 months after completing the vaccine series, blood samples were obtained from 761/984 (77 percent) volunteers enrolled in 13 subtrials. Of these, 748 (98%) also had RFFIT titers equal or greater than 0.1 IU. Finally, 308 persons (52 percent of the initial

volunteers in seven subtrials) volunteered to be bled from 18 to 24 months after vaccination. Ninety-eight percent (303/308) still had titers equal to or greater than 0.1 IU.

The findings in three representative clinical subtrials in which neutralizing antibody titers are presented only for persons from whom successive blood samples were obtained at each indicated time are shown in Table 2. Successive blood samples were obtained from 86 percent (94/109), 74 percent (55/74), and 39 percent (34/88) of volunteers initially enrolled in the respective trials. Two weeks after the third and final injection of RVA, median RFFIT titers in the three subtrials were 6.4, 5.4 and 5.4 IU, respectively. All recipients in these subtrials had neutralizing antibody at two weeks and, in those tested, at six months after vaccination. However, neutralizing antibody titers six months after vaccination were lower than those at two weeks. Eighteen months to two years post-vaccination, median RFFIT titers were from to 0.3 to 1.2 IU and 261/271 (96 percent) of the volunteers had titers equal to or greater than 0.1 IU.

Discussion

The findings summarized in the present study show that the seroconversion rate after pre-exposure vaccination with RVA, given by the currently recommended three dose schedules, approximated 100 percent. However, the duration of the antibody response after initial pre-exposure rabies immunization is as important a concern as the seroconversion rate in evaluating immune responses to rabies vaccines because neutralizing antibody, actively induced by vaccination or passively acquired, is a key factor in protection against rabies infection.[6–9] Yet, determination of the duration of responses to vaccination in sizable populations is complicated by reason of attrition of volunteers. Attrition rates at six months and at nine to 14 months in this study were 9 percent and 23 percent, respectively; these rates probably have little effect on the interpretation of the results in view of the finding that 94 percent of recipients or more had titers equal to or greater than 0.1 IU. On the other hand, even though the attrition rate for those bled 18 months to two years after vaccination was 48 percent, the percent of volunteers showing neutralizing antibody at that time is considered a good approximation of persistence of antibody because titers at two weeks in those who were bled later did not appear different than those in persons who were not bled at the later time.

Although RVA and human diploid cell culture vaccine (HDCV) have not been compared to each other in concurrent clinical trials, the seroconversion rate, persistence of rabies neutralizing antibody, and adverse reactions after pre-exposure immunization with RVA appear practically the same as those obtained with HDCV.[2,10–19]

Health Effects of a Thorium Waste Disposal Site

G. Reza Najem, MD, PhD, and Lisa K. Voyce, MSENE

Abstract: A case-control study of 112 households residing in the vicinity of a thorium waste disposal site found a higher prevalence of birth defects (RR 2.1) and liver diseases (RR 2.3) among exposed than the unexposed group. The numbers were quite small and the confidence intervals wide, however, so that no definite conclusions can be drawn from these data. (*Am J Public Health* 1990; 80:478–480.)

Introduction

Several studies have appeared in the medical literature analyzing possible adverse health effects for persons living in the vicinity of hazardous waste disposal sites.[1–3] To our knowledge there is no published study in which the health effects of a thorium waste disposal site (TWDS) on the general population have been investigated, except for a community-based study in China.[4] That study found no deleterious health effects from exposure to thorium, but had very low statistical power.

The main concern about the possible biological effects of thorium (Th) with a half life of 1.4×10^{10} years is based on its radioactive characteristics and isotopes.[5] Thorium^{232} is the parent of various radio-isotopes including ^{228}Ra (radium), ^{228}Ac (actinium), ^{228}Th, ^{224}Ra, and ^{220}Rn (radon)[5]. Current interest is based in part on increased use of thorium as an energy source, e.g., in reactors using ^{232}Th to produce ^{233}U.[6]

Industrial and mining exposure to thorium have resulted in an increased incidence of lung cancer, pancreatic cancer, colorectal cancers, chronic respiratory diseases, liver damage, and other serious illnesses.[7–9] Skeletal sarcomas, thorotrastomas, and sarcomas of the reticuloendo-thelial system have been reported from a study of patients receiving intravenous injections of thorotrast, a collodial solution of thorium oxide that was used as a contrast medium for diagnostic radiographic studies from the 1930s to the 1950s.[10]

The purpose of this study was to conduct a survey of health effects of a thorium waste disposal site among members of the general population of Wayne, New Jersey, USA.

Thorium Waste Disposal Site

The site is located on a 6.5 acre tract of land in Wayne Township, Passaic County in northern New Jersey, USA.* The population density in Wayne is 1,867.2 per square miles and annual per capita income is $7,725.[11] The thorium waste burial site lies within 100 feet of the sidewalk. Commercial businesses, a nursing home, a school bus maintenance yard, and residential homes are adjacent to the site. A drainage ditch lies at the northern and eastern borders, and drains into a brook at the northeast corner of the burial field. The brook (a tributory to the Pompton River) flows through residential areas (copy of map available on request). Fresh water wetlands lie approximately 1,800 feet to the west of the thorium waste disposal site.* From 1948 until 1971, a company extracted thorium and rare earths from monazite ore, for usage by the Atomic Energy Commission.* During its active years, the plant waste was dumped in backyard sludge piles. The wastes have been buried only in the last few years, after spending over 20 years above the ground.**

Surveys of the New Jersey Department of Environmental Protection showed readings of 40-1491 uR/hour (uR = micro-rad, micro being 10^{-6}) in various regions classified as contaminated areas; Sheffield Brook contamination occurs within 10 meters of both sides. Soil samples revealed Thorium (^{232}Th), Radium (^{238}Ra) and Uranium (^{238}Ur) in the contaminated regions. Water samples from Sheffield Brook and the drainage ditch showed mainly alpha and beta activity.

Most of the air concentrations (ambient and indoor) were within the background radiation levels (approximately 150 mrem/year) The US Environmental Protection Agency (EPA) standard for home concentration is below 4 pCi/liter.***

The residents of the households in the vicinity of the thorium waste disposal site and in the vicinity of contaminated Sheffield Brook have not been tested for radioactive materials uptake.

Methods

The exposed population included 76 households within three blocks adjoining the contaminated areas. The 76 comparison (unexposed) households included all houses located on about 9th and 10th blocks distance from the thorium waste disposal site and contaminated Sheffield Brook. Households were accepted for inclusion in the study if they had resided at the present address for at least five years.

Eleven and 10 households of the exposed and unexposed groups, respectively, did not meet the criteria for eligibility, 10 and nine households, respectively, did not participate in the study due primarily to members not being at home at the time of scheduled interviews or having moved out without leaving forwarding addresses.

Face-to-face interviews of all 112 households (362 members), using a structured questionnaire, were carried out by one interviewer who did not know exposure status; 32 household members who did not agree to a face-to-face

TABLE 1—Demographic Variables among Exposed and Comparison Groups

Variables	Exposed Group	Comparison Group
# of Persons studied	171	191
# of Households studied	55	57
% of Persons Age 50 & over	29	32
% of Persons Age 18 & under	27	26
Duration of Residence		
Mean duration*	13.3 Years	17.2 Years
% Under 10 Years	42	23
% 10–20 Years	23	9
% Above 20 Years	35	68
Annual Family Income		
% Less than $15,000	9	9
% $15,000–$49,000	65	63
% $50,000–$59,000	20	21
% $60,000+	6	7

*Mean duration difference = 3.9 years (95% CI = −.71, −7.23)

interview were interviewed by telephone. For each disease or condition reported by the participants, we asked respondents whether they obtained the diagnostic information directly from their physicians; we did not obtain or review medical records.

The risk ratios associated with the disease were estimated by calculating relative risk ratios.[12] Cornfield's 95% confidence intervals (CI) and Miettinen's 95% CI were computed by using True Epistat computer software.[13] The Mantel-Haenszel method of controlling for confounding variables was used by using the SAS (Statistical Analysis System) computer software.[14]

Results and Discussion

There were no important differences in age, sex, race, income, marital status, or religious affiliation of the exposed and comparison groups, but the comparison group had resided longer in the community (Table 1). There were no differences in smoking history, alcohol consumption, frequency of eating local produce, and history of working in a chemical industry, or in reported history of cancer between the two groups (Table 2).

Although there was a higher prevalence of birth defects and liver diseases among the exposed than the control group, numbers are small and confidence intervals wide (Table 3). After adjusting for duration of residency and alcohol consumption, the estimated risk ratios were very similar, except for 1.1 (95% CI = .05, 78.4) for low birth weight and 2.9 (95% CI = .12, 168.24) for liver diseases.

ACKNOWLEDGMENTS

This study was presented in part at the XI Scientific Meeting of the International Epidemiological Association, Helsinki, Finland, August 1987.

TABLE 2—Comparison of Risk Factors among Exposed and Comparison Individuals and Households

Individuals	Exposed Group (N: 171)	Comparison Group (N: 191)	Risk Ratio (95% CI)
Ever smoked	57 persons	64 persons	0.94 (.63, 1.57)
Ever smoked cigarettes	96% of smokers	94% of smokers	
Average # cigarettes smoked per day	21 cigarettes	18 cigarettes	
Average # of years smoked	19 years	22 years	
3+ alcoholic drinks per day at present	10 persons	12 persons	0.93 (.36, 2.37)
3+ alcoholic drinks per day in past	37 persons	32 persons	1.37 (.78, 2.40)
Drinking 5 oz per week at present	13 persons	25 persons	0.54 (.25, 1.15)

Comparison of Antineoplastic Drug Handling Policies of Hospitals with OSHA Guidelines: A Pilot Study

BARBARA VALANIS, DRPH, KATHLEEN DRISCOLL, JD, AND VIRGINIA MCNEIL, MSN

Abstract: Hospital antineoplastic drug handling policies of 24 hospitals in eight Southwestern Ohio counties were compared with recommendations of the 1986 Occupational Safety and Health Administration (OSHA) guidelines. Although most study facilities where antineoplastics are handled have policies, content varies and is generally less complete than OSHA guidelines, particularly regarding storing, transporting, and disposing of drugs; managing equipment; informing personnel of risk; and surveillance. Recommendations for personal protection concur more closely with OSHA guidelines than do other content areas. (*Am J Public Health* 1990;80:480–481.)

Introduction

Evidence of probable risk associated with staff handling of antineoplastic drugs led the US Occupational Safety and Health Administration (OSHA) to issue comprehensive guidelines covering staff training and surveillance; use and care of protective equipment, apparel, and techniques; and storage, disposal, and transport of drugs and contaminated equipment.[1] Concerned about moral and legal issues, many hospitals have also developed institutional policies.

This study investigated the status of facility policies for handling antineoplastic drugs in hospitals and home health care agencies in eight southwestern Ohio counties and compared policy content to OSHA guidelines.

Methods

In July 1986, a questionnaire, modeled after Tortorici's[2] was mailed to the directors of the 32 hospitals and 25 community health agencies in the eight predominately rural counties comprising Region I of the Cancer Control Consortium of Ohio. Respondents were requested to enclose their facility's antineoplastic drug handling policy. Policy content was compared with that of the 1986 OSHA guidelines using an investigator-designed tool for systematically coding content relative to OSHA guidelines. For each item, the facility policy is rated 0 if the item is absent and 1 if the item is included. The instrument yields a maximum total score of 219 and five subscores: 1) General Guidelines (37); 2) Protective Equipment (14); 3) Facilities for Mixing and Storing Agents (15); 4) Protective Apparel (49); and 5) Protective Techniques (104). The content analysis was conducted by one investigator (KD).

Results

Twenty-four hospitals and 11 community health agencies responded, a response rate of 75 percent for hospitals, 44 percent for home health agencies. Administrators of 20 of the hospitals report antineoplastics are mixed and administered at their facility and one home health agency administers premixed antineoplastics; 18 of the 20 hospitals and the home health agency have implemented an antineoplastic drug handling policy. Eleven hospitals submitted their policy for analysis.

All 11 policies are less comprehensive than OSHA guidelines. Total policy scores of individual facilities ranged from 26 to 92 of a possible 219. The mean total score was 50.6 (median score 41). Areas least addressed under "General Guidelines" were maintaining files on specific antineoplastic agents and providing staff with information on known risks, medical policies, safe handling of investigational drugs as they are introduced, and follow-up evaluation of staff knowledge and competence regarding antineoplastic drug handling. Least addressed under "Protective Equipment" were procedures for installation, maintenance, and decontamination of hoods, while unaddressed content under "Facilities for Mixing and Storing Agents" related to reserving a hood only for mixing antineoplastics, posting warning signs, listing drugs covered by cytotoxic policies, and labeling stored antineoplastics. Under "Protective Apparel" recommendations for use of protective apparel during drug mixing conformed better to OSHA guidelines than recommendations for administration, while those for excreta handling and cleaning up spills were generally inadequate. Recommendations for glove and gown use were more often consistent with OSHA recommendations than for use of masks or eye protection. Under "Protective Techniques" least frequently

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health*, 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

Improving Influenza Vaccination Performance in an HMO Setting: The Use of Computer-Generated Reminders and Peer Comparison Feedback

MARY B. BARTON, BA, AND STEPHEN C. SCHOENBAUM, MD, MPH

Abstract: We evaluated a program for improving influenza immunization performance in a health maintenance organization (HMO). The HMO implemented several interventions successively from 1984–87: a postcard reminder to members at high risk for complications of influenza, a computer-generated reminder to the physician at the time of any primary care visit by high-risk patients, performance feedback to chiefs of service, and, finally, retrospective feedback to each physician comparing his/her performance with that of the other physicians. We examined immunization rates for a group of members older than age 65, a high-risk group under age 65, and a group of diabetic members who had not been subject to the reminders (vs a group who had been covered by the program).

Vaccination rates were increased in those diabetic members who received reminders. Nevertheless, among members younger and older than age 65 whose experience was observed over three flu seasons, a significant increase in vaccination rates was not achieved until physician feedback was added to the program. We conclude that each element of the reminder and feedback program has contributed to the overall increase in vaccination rates at the HMO and that effective ongoing influenza immunization programs can be implemented in practice settings with appropriate systems support. (*Am J Public Health* 1990; 80:534–536.)

Introduction

Influenza accounted for more than 10,000 excess deaths in the United States in 19 different epidemics between 1957 and 1986.[1] Yet, an influenza vaccine containing a strain similar to that causing epidemic disease has been found to be up to 80 percent effective at protecting the elderly, chronically ill population against hospitalization and death from acute respiratory disease during an influenza epidemic.[2] With the goal of reducing excess morbidity and mortality from influenza, the Immunization Practices Advisory Committee (ACIP) of the Centers for Disease Control recommends the annual vaccination of specific groups with chronic medical conditions who are at high risk for complications of influenza. In the early 1980s, the US Public Health Service's stated goal was vaccination of 80 percent of those at highest risk for morbidity and mortality from influenza infection. Unfortunately, estimates indicate that fewer than 25 percent of high-risk individuals were receiving an influenza immunization each year.[3]

Despite the good intentions of their physicians, Americans do not necessarily receive the benefits of available preventive health measures such as cancer screening and immunizations.[4] Several randomized controlled trials have shown that systems for physicians, such as reminders and feedback, can improve delivery of preventive measures.[5–7] In addition, postcard reminders to patients have been shown to increase influenza vaccination among elderly populations, including those in a health maintenance organization (HMO) setting.[8–10] Although these trials demonstrate the efficacy of practice support systems, there is little evidence that reminders and feedback actually have been adopted in practice settings or that they are effective in an ongoing practice-based program as distinct from a special study. The Health Centers Division of Harvard Community Health Plan (HCHP) is a large staff model HMO in the Boston area. Most of HCHP's health centers use a computerized medical record system for documenting ambulatory care.[10] This system has also been used as a tool in controlled trials of limited size to monitor clinician performance and provide feedback.[7,12]

In recent years HCHP has instituted a program to improve influenza vaccination of its high-risk members. The program includes educating members about the need for and availability of flu vaccine and consists of a series of systems for member reminders, physician reminders, and physician feedback on performance. The program has developed in increments. The HMO has not considered it to be research but rather part of its efforts to improve clinical operations and quality of care. This paper presents a description of the program as it has evolved, an evaluation of HCHP's influenza immunization performance and an assessment of the effectiveness of the reminder and feedback systems.

Methods

The membership of the Health Centers Division of HCHP grew from 178,000 in 1984–85 (Flu Season #1 in this evaluation) to 227,000 in 1986–87 (Flu Season #3). During that time, an average of approximately 100 internists practiced adult primary care at seven health centers in the metropolitan Boston area.

The first year's intervention involved postcard reminders to HMO members, educational materials (e.g., posters for waiting areas and examination rooms, pharmacy bag notices), and a reminder message to clinicians at the front of the summary of the computerized record which was prepared for each scheduled primary care visit for a high-risk patient under age 65. This was supplemented in the second year by chart reminders for persons over age 65 and feedback of performance to service chiefs. In the third year these actions were further supplemented by feedback of performance to individual physicians and by the periodic distribution to physicians of lists of patients not yet immunized.

In 1983–84, the year before the influenza vaccination program began, a survey of records of members age 65 and over revealed immunization rates of 24 percent in centers using the automated record and 22 percent in the one health center using a manual record. In order to detect change in vaccination rates over the three succeeding flu seasons, we selected a cohort of members representing the high-risk group under age 65 and a cohort of members age 65 and over.

The latter were chosen from among those members who had belonged to HCHP for four or more years as of June 1987, had turned 65 by September 1984, and had designated a specific physician as their primary provider. Lists of members meeting these criteria were obtained for each health center and stratified by provider; a random sample was then selected from each center's list. By using computerized enrollment files it was possible to generate a similar list for the center not using the automated medical record.

The cohort of persons under age 65 at high risk for complications for influenza was identified from the computer-generated list used to send out reminder postcards in early autumn and to flag charts with a reminder message at the time of flu season visits. The computer algorithm used to create this list consists of a search for certain diagnostic codes corresponding to high-risk categories which were entered during a specific window of time in the prior year (roughly October 1-June 1 each year).

In order to assess the specific effect of a reminder, we focused on a single diagnostic group—persons with insulin-dependent diabetes: HCHP maintains a Plan-wide registry of insulin-dependent diabetics culled from diagnostic codes entered in the computerized medical records and also from all pharmacy slips recording prescriptions for insulin. In comparing this list with the flu vaccine reminder list for Flu Season #3, some members from centers with the automated record were identified who were not on the reminder list despite their having a high-risk diagnosis. Reasons for diabetic members not appearing on the flu vaccine reminder list include: joining HCHP after the flu vaccine reminder list had been made for the year, having no visit to HCHP during the window of time that computer records are searched for high-risk diagnoses, transferring care to another health center and thus a different member identification number, or having a very recent initial diagnosis of insulin-dependent diabetes mellitus (i.e., after the search window for creating the reminder lists).

Because the mean age of the non-reminder group (40.8 years) was significantly lower than that of the overall group of diabetics under age 65 on the vaccine reminder list (48.3 years), we used the subset of both groups between the ages of 40 and 65 for comparison of vaccination rates (respective mean ages ± SEM: 53.4 years ± .7 and 54.5 years ± .5).

Records of members at the computerized centers were searched by computer for the therapy code for influenza vaccine. Records for members at the non-automated center were reviewed by hand.

Data analysis was performed using SAS version 5.

Results

The overall vaccination rates at the computerized centers for the three flu seasons starting in 1984 are shown in Table 1. Vaccination rates increased substantially in both cohorts in Flu Season #3 (1986–87), which corresponded to the institution of the physician feedback mechanism. Immunization rates at the center without the automated record remained stable at 24–33 percent throughout the three flu seasons.

The focused study of diabetic members revealed that those on the reminder list were both more likely to have a visit during flu season and more likely to be vaccinated if they had a visit to their primary clinician (Table 2). The difference in visit rates probably reflects the effect of the postcard reminder on encouraging flu season visits. It is important to

TABLE 1—Influenza Immunization Rates in an HMO during Flu Seasons #1–3, 1984–1987

#1	42		38	
		0 (−5, 5)		3 (−7,13)
#2	42		41	
		22 (17,27)		14 (4, 24)
#3	60		55	

*Difference between rates in successive seasons (95% confidence limits)

TABLE 2—Vaccination Status of Diabetic HMO Members, Ages 40–65

Vaccination Status	Reminder (%)	No Reminder (%)	Difference*
Vaccinated	55.9	27.0	28 (16, 40)
Patient refusal	0.0	1.8	−2 (−4, 0)
Not indicated	4.9	1.8	3 (−1, 7)
No flu season visit	23.8	33.3	−10 (−21, 1)
Not vaccinated despite a flu season visit	15.4	35.1	−20 (−33, −7)
Total in group	143 (100.0%)	111 (100.0%)	

*Difference in percentage between reminder and no reminder groups (95% confidence limits)

recall, however, that the reasons that prevented the "no reminder" group from being included on the computer's flu vaccine reminder list are directly related to lower visit rates in the previous year and these reasons may contribute to the continued lower visit rate in this group. In contrast, the difference in vaccination rates for those with visits—73 percent for those receiving the reminder versus 42 percent for those not getting the reminder—ought to reflect the effect of the computer-generated chart reminder on the physician.

Discussion

As noted at the outset, there have been several controlled studies of various interventions to improve performance of periodic health measures. All have shown efficacy of the specific intervention under study. None, however, has been a demonstration of sustained program effectiveness; nor has any of the studies attempted to determine the effect of additive interventions. The present report demonstrates that it is possible to achieve improvement in annual influenza vaccination performance in a practice setting using a combination of reminder and feedback techniques.

At least one other HMO has reported achieving performance similar to HCHP's but with a different combination of techniques. Group Health Cooperative of Puget Sound (GHC), which has a large elderly population, has reported vaccination rates for its members over age 65 of 48 and 53 percent in 1986–87 and 1987–88, respectively.[13] GHC sends reminder letters to its members over age 65, since they can be identified from automated enrollment files. The program runs mass vaccination clinics over a period of several weeks. Volunteer senior citizens help staff the clinics. The program, however, does not specifically target younger persons at high risk of complications of influenza.

HMOs can increase the cost-effectiveness of influenza vaccine delivery both by running mass immunization clinics and by appending the immunization process onto an encoun-

ter which was precipitated for another reason. In either case the cost per immunization delivered should be less than if a specific visit has to be set aside solely for vaccination.

The routine data on the flu program generated from HCHP's annual feedback show that in the centers with the computerized medical record approximately 70 percent of those members on the reminder list who visit their doctor during the flu season actually get the vaccine; 15 percent refuse; and for 15 percent there is no documentation of whether they were offered vaccine, got it, or refused. These are very positive results: many more HCHP members thought to be at greatest risk of complications from influenza, persons with chronic cardio-pulmonary disease under the active care of physicians, get vaccinated than national[3] or local[14] statistics indicate occurs elsewhere. Since physicians appear to be able to give the vaccine at HCHP and patients appear to be willing to accept it most of the time it is offered, neither physicians nor patients seem to be major barriers to more effective vaccination.

As a result of the evaluation, HCHP has continued the influenza immunization program, including: postcard and chart reminders for all members over age 65 and high-risk members under age 65, periodic distribution of lists of unimmunized members to clinicians during the vaccination season, and feedback of performance statistics to individual clinicians and chiefs of service. Since the basic computer programming of the reminders has been completed and the computer generates the lists and statistics for feedback, this influenza immunization program requires a minimum of effort to sustain.

Tobacco Excise and Declining Tobacco Consumption: The Case of Papua New Guinea

SIMON CHAPMAN, PHD, AND JEFF RICHARDSON, PHD

Abstract: Excise elasticities of demand for non-cigarette tobacco and cigarettes were calculated for Papua New Guinea for the 14 years 1973–86. Respectively, these were −0.50 and −0.71. This means that 10 percent increases in cigarette and non-cigarette tobacco excise are associated with an estimated 7.1 percent fall in demand for cigarettes and a 5 percent decrease in the demand for tobacco. As tax (excise) elasticities would normally be significantly smaller than price elasticities, these results imply that the consumption of cigarettes and tobacco in Papua New Guinea are more responsive to prices than in the United States and other Western countries. The level of excise is therefore an important and practical instrument for the control of consumption. These elasticities appear to be the first reported for a developing country. It is suggested that if they are indicative of consumer behavior in lower income countries then increasing tobacco and cigarette excise should be considered as an important strategy for the control of smoking in these countries which, because of their large populations, are huge markets for tobacco products and thus major targets for tobacco control measures. (*Am J Public Health* 1990; 80:537–540.)

Introduction

An expert working group convened by the American Heart Association recently recommended an increase in the rate of excise taxation on tobacco products and the resulting increase in tobacco prices as the leading priority for the United States among a range of smoking control strategies.[1] The success of the strategy would be directly proportional to the elasticity of demand which is defined as the percentage change in quantity demanded divided by the percentage change in price. Recent studies indicate that the price elasticity of demand for cigarettes by adults in the USA is approximately −0.4, meaning that a 10 percent increase in price should create a 4 percent decrease in demand.[2] A substantial portion of this decrease seems to result from a decrease in smoking prevalence through cessation and falling incidence, rather than through less smoking by continuing smokers.[2]

The elasticity of demand for cigarettes has been shown to be considerably greater in groups with lower levels of disposable income, namely teenagers (−1.4)[3] and people of low socioeconomic status[4]; such groups will stop smoking at a faster rate than those with higher disposable incomes if the price of cigarettes rises, and they may be influenced to not start smoking because of the additional financial burden. However, no studies appear to have been published on the effects of price changes on demand in developing countries, where disposable incomes are typically very low. Despite this, per capita consumption of cigarettes and smoking prevalence in some places is rising at alarming rates,[5] and the promotional activities of the tobacco industry are generally unchecked by any government regulations.[6]

Smoking in Papua New Guinea

Papua New Guinea (population 4 million) is located immediately to the north of eastern Australia. In 1987, it had a gross national product of per capita of $700(US), placing it 48th (equal with Swaziland) in the World Bank's ranking of poor countries.[7] Its population is predominantly Melanesian and it is governed from the coastal city of Port Moresby. Civil unrest and change in government have been common since independence. No national smoking prevalence surveys have been undertaken, although a 1981 survey conducted in two regions found rates as high as 85 percent among coastal Papuan men and 80 percent among highland women from Goroka.[8] The last published Household Expenditure Survey (1975/76) found that tobacco products accounted for 5.2 percent of average household expenditure, placing them after rent (10.5 percent), beer (7.2 percent), rice (5.6 percent), transport (5.3 percent) as the fifth most significant item in weekly expenditure.[9]

Smoking control policies and programs in Papua had been non-existent until the introduction of the Tobacco Products (Health Control) Act 1987 in November of that year.[10] The Act banned tobacco advertising; reportedly this ban has not been widely implemented. There are no health warnings on cigarette packs or advertisement, health education about smoking is negligible, and there has been neither public debate nor any regulation of smoking in public areas. Tobacco advertising and sports sponsorship both remain widespread, with the most remote bush trading posts typically being bedecked with posters advertising brands marketed by two Australian subsidiaries of transnational tobacco companies, i.e., W. D. and H. O. Wills and Rothmans. Cigarette advertising is almost certainly the most common form of outdoor advertising although no data are available on expenditure and consequently could not be included in our analysis.

Methods

Demand equations are usually estimated by regressing the quantity of the commodity demanded against the price of the commodity, the price of its close substitutes, and disposable income. Depending upon the commodity and the purpose of the analysis, other variables which influence demand may be included, such as advertising and health education expenditures.

In order to estimate the impact of taxes on consumption, a second equation must be estimated relating the level of taxation to the price level. This, in conjunction with the results of the demand equation may be used to infer the tax-consumption relationship. Regrettably, this conventional methodology could not be applied to the Papua New Guinea

experience. Our inquiries about the contributions of wholesale and retail mark-ups to retail price were fruitless. Instead, the government statistical office in Port Moresby was able to provide information on the volume of cigarettes and non-cigarette tobacco consumed and the excise revenue obtained from these for the years 1973–86 (Table 1).

The use of excise rather than price data makes direct comparison of these findings with those obtained in other countries problematic although we believe our conclusions have important implications for policy since it is excise, and not usually retail price, that governments are able to manipulate directly. As excise tax is only a portion of retail price, excise elasticity is likely to be less than and so an *understatement* of the full price elasticity, thus suggesting that the elasticities shown below are quantitatively smaller than the relationship between retail price and demand. The two equations referred to above may be combined into a single equation which directly relates consumption to taxation. More formally, equations (1) and (2) below (which are usually estimated in demand studies) imply equation (3) which is the subject of the analysis here.

$$\text{Consumption} = f_1(\text{price}, X) \quad (1)$$

$$\text{Price} = f_2(\text{excise}, Y) \quad (2)$$

hence

$$\text{Consumption} = f_3(\text{excise}, X, Y) \quad (3)$$

where X and Y are sets of other relevant variables.
Equation (3) is a "reduced form" equation. Unlike the structural equations (1) and (2), it does not describe the direct, behavioral relationships between variables. More specifically, equation (1) embodies the fact that consumers react directly to market price and not to excise taxes. However, as retail price reflects taxes there is an indirect relationship which may be legitimately estimated. The resulting "excise elasticity" would not indicate the price elasticity of demand except under particular circumstances, i.e., when prices rise in direct proportion to taxes. If wholesale prices rose proportionately less than taxes (or remained unchanged or fell) then the percentage change in price would be less than the percentage change in tax and the excise elasticity would underestimate the magnitude of the price elasticity.

TABLE 1—Tobacco and Cigarette Consumption, Excise Tax Rate and Consumption Expenditure per Capita, Papua New Guinea 1973–86

Date	Quantity Tobacco kg/capita	Quantity cigarettes kg/capita	Excise Tax Rate Tobacco kina/kg	Excise Tax Rate Cigarettes kina/kg	Consumption Expenditure per Capita
1973	0.53	0.26	2.05	15.22	319.65
1974	0.39	0.22	2.45	20.03	263.56

1984	0.26	0.30	3.07	16.04	317.48
1985	0.25	0.26	2.95	16.50	312.57
1986	0.27	0.26	2.80	16.37	—

The estimated "excise elasticity" would be biased if excise taxation correlated with one of the other variables and this variable was not included in the estimation procedure. The most important "other variables" in such analyses are the level of personal income per capita and the cost of production. As no information was available on personal income, data were obtained on a closely related measure, i.e., private consumption per capita. No data were available to act as a proxy measure for production costs. However, it appears most unlikely that these would correlate with annual changes in excise tax. Consequently, the regression coefficient should produce an unbiased estimate of the excise elasticity.

The data in Table 1 were used to estimate "demand" equations using ordinary least squares regression techniques and a multiplicative model shown below.

$$Q_i = e^{a+\beta 4T} E_i^{\beta 2} E_j^{\beta 2} C^{\beta 3}$$

where:
a = constant estimated by the regression
$\beta 1, \beta 2, \beta 3, \beta 4$ = coefficients estimated by the regression. Because of the multiplicative model, $\beta 1, \beta 2, \beta 3$ are the elasticity coefficients
Q_i = quantity of product i per capita (in kg)
E_i = excise per kg of product i (inflation adjusted kina)
E_j = excise per kg of the substitute product j
C = total consumption expenditure per capita on all goods and services
T = a trend variable (1 in 1973; 2 in 1974; 2 in 1975 etc)
a_o = constant
The multiplicative model is used as it has simple but acceptable theoretical properties and it may be readily estimated with a logarithmic transformation of the variables.

The resulting coefficients $\beta 1$-$\beta 3$ may be interpreted as "excise elasticities" and "cross excise" elasticities. Thus, for example, in the equation for cigarettes, a 10 percent change in excise E_1 will be associated with a $10\beta_1$ percent change in the consumption of cigarettes (Q_1); a 10 percent change in the excise on the substitute, tobacco, will result in a $10\beta_2$ percent change in consumption. As it is the level of excise tax which may be directly varied by government and not generally consumer prices, the model is relevant for the policy issue of controlling consumption.

Results

Results for the two demand equations are reported in Table 2. A very high percentage of the variation in the quantity demanded is explained by the variables in the model as would be expected in a time series analysis. The "income" elasticity in both cases is positive and has a plausible magnitude. Surprisingly, the income effect for cigarettes is smaller than that for non-cigarette tobacco. As expected in the case of non-cigarette tobacco, there is a negative value for the trend variable. The coefficient suggests that, after allowing for the effect of the other variables in the model, non-cigarette tobacco consumption has declined about 5

TABLE 2—Regression Equation Results for the Quantity of Tobacco and Cigarettes per Capita

	Q (tobacco)		Q (cigarettes)	
Dependent Variable	B	SE	B	SE
Tobacco excise	−0.50*	0.08	0.50	0.09

Income	1.37*	0.30	0.86	0.34
Trend	−0.05*	0.006	−0.008	0.006
Constant	−9.84	2.13	−4.68	2.45
R^2	0.95		0.93	
Standard Error	0.06		0.07	
dW	2.30		2.19	
n	14		14	

Notes: The first column of each result gives the estimated regression coefficient ( ) and the second column, the Standard Error. the logarithm of all variables has been used.
T (Trend variable) = 1, 2, 3, . . . 14

percent per annum.* No trend is apparent for cigarettes. The most important results in Table 2 are for the excise variables. For tobacco and cigarettes the excise elasticities are −0.50 and −0.71, respectively.** In both cases, excise "explains" a very high proportion of the variation in the quantity demanded. The results indicate that there was a strong relation between declining per capita cigarette consumption and rising excise. All else being equal, a 10 percent increase in cigarette excise has been associated with a 7.1 percent fall in cigarette consumption; and a 10 percent increase in non-cigarette tobacco excise with a 5 percent in its consumption. The "cross excise elasticities" (which due to the limited data have been unconstrained) are 0.62 for non-cigarette tobacco and 0.50 for cigarettes. That is, there is the expected positive sign in both cases.

Discussion

On the basis of the evidence presented here it would appear that the elasticity of demand for cigarettes and tobacco in Papua New Guinea is much greater than has been estimated for the USA and other Western nations in recent years. As excise is only a fraction of the final retail price, a change in excise would normally be expected to cause a proportionately smaller change in price which implies that the price elasticity exceeds the excise elasticity of demand. Irrespective of the relative magnitude of these coefficients, the present results suggest that the consumption of tobacco products can be manipulated through variations in the excise rate. If these demand characteristics are typical of developing countries, this finding may have enormous implications for smoking control in the Third World. Such countries often have diverse linguistic subcultures which mitigate against mass communication in health education. Being oriented toward problems of infectious disease and malnutrition, their health services typically accord low priority to smoking control. With the exception of a small number of developing countries in which tobacco is a major industry—e.g., Brazil, Zimbabwe, Malawi, Thailand, India—most developing nations have a deficit balance of trade in tobacco, with imports requiring the expatriation of growing amounts of hard currency to the exporting transnationals or state monopolies.[6]

Tobacco's main attraction to such economies lies in the ease with which its consumption can be taxed. However, excise taxes represent only transfer payments within economics whereas money lost overseas in paying for tobacco imports represents a genuine drain on a nation's balance of payments. As such, countries such as Papua New Guinea with deficit tobacco trade should not balk at easily implemented measures that reduce tobacco consumption if the resultant economic and public health advantages could be effectively communicated to key officials and "extraneous" factors like corruption and bribery exposed or otherwise circumvented.

In the short to medium term, an excise-led smoking control policy can reduce smoking and simultaneously satisfy Treasury requirements for what is an easily collected and bountiful source of revenue. Our results suggest that a 10 percent increase in cigarette excise will decrease consumption by about 7.1 percent, therefore increasing total excise collections. A 10 percent increase in tobacco excise will similarly increase total collections as the percentage increase in excise exceeds the percentage decrease in the volume consumed. Eventually, a threshold would be reached where the decline in consumption caused by rising prices would produce diminishing total excise. However, this point will, in many cases, be well in the future and therefore of less concern to political decision-makers than the attractions of both a short-term gain to state finances and falling smoking prevalence.

By World Bank projections,[7] the population of developing countries by year 2000 will constitute 80 percent of world population. Further, the aggregate rate of increase between 1987–2000 of the populations of developing countries is estimated to be 28 percent compared to a forecast increase of only 8 percent in the population of industrial market economies. Cigarette consumption is decreasing in the industrialized world at about 1 percent per year, whereas in Asia and Latin America it is growing 7 percent faster than the population and, in Africa, 18 percent faster. If the results of the excise elasticity analysis we have provided are found to be typical of those in developing countries, then excise policy could be a powerful instrument in controlling smoking in these vast markets. Its use could reduce tobacco consumption rapidly, possibly faster than any other realistic instrument of public health policy and hence produce health benefits for many millions of people.

*The results are not the consequence of a correlation between income and trend. The coefficient of a correlation between these two variables is only 0.206. More generally, the correlation table does not suggest a problem of multicollinearity. (Data available on request from the authors.)

**This latter coefficient is increased to −1.08 if two further years (1971, 1972) are added to the data set. Excise data provided for these two years were outliers (33.98 and 34.49 kina/kg) and in the absence of any explanation for their large difference, we have omitted them from our main analysis, suspecting typographical error.

WHO Fellowships for Travel/Study Abroad

The World Health Organization (WHO) will provide a limited number of short-term fellowships for use during 1991 for travel/study abroad related to the improvement of health status in the United States. This support is limited to US citizens employed in the health field.

Fellowship awards are offered to persons employed in educational or service aspects of the health field with government agencies, educational institutions, or non-profit organizations. Applications cannot be considered for basic laboratory bench research or attendance at international meetings or seminars. In addition, undergraduate or graduate students including medical interns and residents, self-employed health care providers, or individuals employed by profit-making organizations are not eligible.

The fellowship award provides per diem, transportation, and a small stipend to cover miscellaneous expenses. Employers of applicants are expected to endorse the application and agree to continue the applicant's salary throughout the fellowship period. Except in unusual circumstances, the fellowships will be limited to short-term programs of one or two months. The number of fellowship awards will be governed by the funds available.

The *deadline* for the submission of the completed application is September 30, 1990.

Further information and application form may be obtained from the Secretary, WHO Fellowships Selection Committee, Health Resources and Services Administration, 5600 Fishers Lane, Room 14-14, Rockville, MD 20857. Telephone: (301) 443-6152.

Smoking Before, During, and After Pregnancy

LOIS A. FINGERHUT, MA, JOEL C. KLEINMAN, PHD, AND JULIETTE S. KENDRICK, MD

Abstract: We report the first national data on smoking before, during, and after pregnancy. Estimates are based on the 1986 Linked Telephone Survey that reinterviewed 1,550 White women 20–44 years of age who were respondents to the 1985 National Health Interview Survey. An estimated 39 percent of White women who had smoked before pregnancy quit smoking while pregnant (27 percent when they found out they were pregnant and 12 percent later during pregnancy). Women with less than 12 years of education were five times as likely to smoke and one-fourth as likely to quit as those with 16 or more years of education. Women who smoked more than one pack of cigarettes per day before pregnancy were one-fifth as likely to quit as those smoking less. Of the women who quit, 70 percent resumed smoking within one year of delivery. Of those who relapsed, 67 percent resumed smoking within three months of delivery and 93 percent within six months. There is little evidence of educational differentials in relapse rates. The fact that relapse remains high suggests that while health of the fetus is a strong influence on women's smoking habits, women may be less aware of the effect of passive smoke on the infant. (*Am J Public Health* 1990; 80:541–544.)

Introduction

Increased risks of fetal and infant death and low birthweight have been linked to maternal smoking[1–3]; even if smoking is stopped late in pregnancy, there will be a positive effect on the infant's birth weight.[4,5] The effects of passive smoke on nonsmokers, and especially on young children, have also been shown to be harmful.[6–9]

For those women who smoke, pregnancy can be viewed as an ideal time for cessation: quitting can affect the health of their unborn child as well as their own health. It is also a time when contact with health professionals is very frequent. Thus there is substantial opportunity for health providers to have an impact on maternal and infant health through smoking cessation.

Among pregnant women, the proportion of married mothers 20 years of age and over who smoked before their pregnancy decreased between 1967 and 1980, while the proportion of those women who quit smoking after they found out they were pregnant increased.[10]

In this study, we report national data, the first ever available, regarding the frequency and timing of smoking relapse among women who quit smoking while pregnant.

Methods

Data Sources and Limitations

The National Health Interview Survey (NHIS) is a multistage stratified probability sample of the household population of the United States. In 1986, a linked telephone survey was conducted that reinterviewed respondents to the 1985 NHIS. The primary purpose of the telephone survey was to test methodology[11]; it included a battery of questions on smoking before, during, and after pregnancy. The target sample was selected from women responding to the NHIS during January–June 1985: nearly 2,000 women 18–44 years of age who either were pregnant at the time of the 1985 NHIS or whose most recent birth occurred during the five years preceding the NHIS. The women were interviewed using a computer-assisted telephone interview system during March–May 1986.

Definitions

- *Women who smoked prior to pregnancy* are those women who said that they smoked at least one cigarette per day during the 12 months before they found out they were pregnant. Women who said that they did not smoke regularly were not included as smokers prior to pregnancy.
- *Women who quit smoking while pregnant* are those who smoked prior to pregnancy and "quit early" (quit when they found out they were pregnant) or "quit later" (quit at a later time during their pregnancy). Those who quit early were not asked whether they resumed smoking prior to delivery. However, data from a large clinical trial of smoking during pregnancy show that very few women who quit early in pregnancy resume smoking before delivery.[12] Those who quit later continued to smoke cigarettes after they found out they were pregnant, but said that they quit for at least a week during their pregnancy and did not start smoking again before delivery; they were not questioned about when quitting occurred.
- *Women who relapse* are those who quit while pregnant and then resumed smoking within one year of the delivery.
- *Postpartum smokers* include women who relapsed within one year of delivery; women who continued smoking during the entire pregnancy and were still smoking within one year of the delivery; and women who smoked during the year after delivery even though they had not smoked in the 12 months prior to delivery.

The number of cigarettes smoked before pregnancy was dichotomized into less than 20 vs 20 or more cigarettes per day. Age of mother, education, and marital status were determined at the time of the 1985 NHIS.

Response Rates

The response rate to the first six months (January–June) of the 1985 NHIS was 96 percent.[13] Of these respondents, 86 percent completed the telephone followback survey yielding a sample of 1,918 women. Non-respondents included primarily refusals and those women with changed telephone numbers who could not be tracked.[11] In addition to excluding nonrespondents, 28 sample women who did not respond to

This paper, submitted to the Journal August 9, 1989, was revised and accepted for publication November 21, 1989.

the entire battery of smoking questions were omitted from the analysis.

As there were relatively few Black women in the sample (n = 278), this analysis is limited to White women. Further, there were only 35 White teenagers in the original sample and because teenagers are known to have different smoking habits than adults,[14] the analysis is limited to White women 20–44 years of age. The overall response rate for these women was 88 percent, yielding a final sample of 1,550 women.

For White women 20–44 years of age, response rates were higher for married than for unmarried women (90 vs 83 percent), and for those with at least a high school education than for those with less education (91 vs 78 percent). All percentages are weighted to reflect national estimates of women in the civilian noninstitutionalized population of the United States.

Analysis

The proportions and standard errors in this analysis were computed using the SESUDAAN program that takes into account the complex sample survey design of the NHIS.[15] Multiple logistic regression analysis was performed using the Proc Logist procedure within SAS.[16] Because the design effects were small (less than 1.2, based on the ratio of standard errors from SESUDAAN to simple random sample standard errors), standard errors were approximated using weighted estimates in the logistic regression procedure normalized to reflect the sample size (NORMWT option in SAS). The results of the logistic regression are presented as adjusted odds ratios with 95 percent confidence intervals calculated by taking the anti-logarithms of the regression coefficients and corresponding confidence intervals.

Results

One-third of White women 20–44 years of age said that they smoked cigarettes prior to pregnancy. Older women were less likely to smoke than younger women; and married women were much less likely than unmarried women to have been smokers. The prevalence of smoking decreased sharply with increasing education (Table 1).

Using multiple logistic regression to control for age and marital status, White women with less than 12 years education were five times as likely as college graduates (16 or more years education) to have smoked prior to pregnancy. Similarly, White unmarried women (controlling for age and education) were twice as likely as married women to have smoked. Women in their 20s were about 40 percent more likely to smoke than women in their 30s and early 40s (Table 1).

Of the White women who said they smoked, 39 percent indicated that they quit while pregnant (27 percent early and 12 percent later during pregnancy) (Table 2). The Health Promotion and Disease Prevention (HPDP) supplement to the 1985 NHIS estimated that 21.2 percent of all women 18–44 years quit smoking when they learned they were pregnant.[17] Further analysis of the HPDP data show that among White women 20–44 years of age, 24.2 percent quit smoking early in pregnancy. This estimate is not significantly different from our estimate of 27.4 percent.

Sixty percent of college graduates quit compared with 28 percent of those with less than 12 years education. Women who were lighter smokers prior to pregnancy were much more likely to quit than were heavier smokers.

Based on the logistic regression results, the relation between quitting and education was nearly as strong as between smoking and education. The amount smoked prior to pregnancy was also strongly associated with quitting. Age and marital status had little effect on quitting (Table 2).

In all, 70 percent of White women who quit smoking while pregnant resumed smoking within one year. This may be a slight underestimate since there were eight women who quit smoking while pregnant but who had less than a year of exposure time—from delivery to interview—in which to relapse and therefore were not considered relapsers. Unlike "smoking prior to pregnancy" and "quitting," there is little association between education and relapsing (Table 3). However, one year relapse rates are higher for those who quit later during pregnancy as opposed to those who quit when they found out they were pregnant (81 vs 66 percent).

Based on the regression results, younger women, women who were heavy smokers prior to pregnancy, and women who quit smoking later during pregnancy were more likely to relapse. However, the relatively small numbers of women who quit smoking (n = 191) result in rather wide

**Based on multiple logistic regression.

confidence intervals for all of these estimates (Table 3). Age of mother and time of quitting (early vs later) were the only factors for which the confidence intervals came close to excluding 1.0.

Of all White women who quit smoking while pregnant, 27 percent relapsed within a month of the delivery, and 52 percent relapsed within 4 months (Figure 1). Those women who quit later during pregnancy resumed smoking much sooner than women who quit smoking earlier in their pregnancy; 69 percent of the former group relapsed within three months of the delivery compared with 37 percent of the latter group of women.

The net effect of quitting and relapsing is the prevalence of smoking one year postpartum. The estimate includes women who relapsed within a year, those who did not quit during their pregnancy, and those who smoked postpartum but said they were not smoking before or during their pregnancy. (This latter group is small—only 2 percent of the total sample.) The great majority, 87 percent, of the women

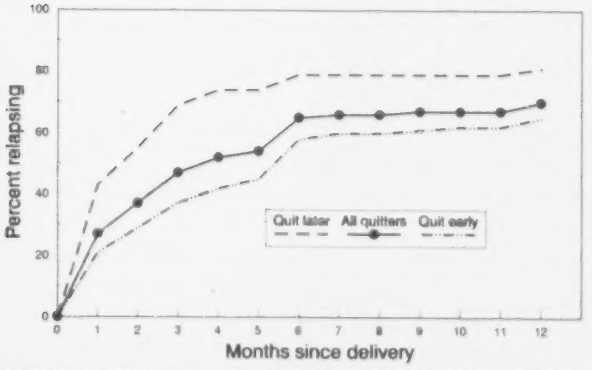

FIGURE 1—Relapse Rates among White Women Ages 20–44 Years Who Quit Smoking While Pregnant (data are from the 1986 Linked Telephone Survey)

who smoked prior to pregnancy were also smokers one year after delivery. Hence, the prevalence of smoking one year after the delivery was only slightly lower than before pregnancy; 30.3 vs 32.0 percent. Postpartum smoking has similar associations with age, marital status and education as shown in Table 1 for smoking prior to pregnancy.

Prenatal Care and Smoking

Nearly all (99 percent) of the women said that they received prenatal care during their pregnancy. Those who smoked prior to pregnancy were less likely to begin prenatal care in the first trimester than those who did not smoke during this period (90 percent vs 95 percent). Those smokers who quit while pregnant were more likely to have begun care in the first trimester than those who did not quit, 94 vs 88 percent.

Regardless of whether a woman went to a clinic or to a private physician for prenatal care, about three-fourths of the smokers prior to pregnancy said that a doctor had advised them to quit or cut down on smoking during their pregnancy (57 percent who quit smoking and 83 percent who did not quit).

In response to a question about different methods used to quit or help cut down on smoking, about 95 percent of the women who quit smoking stated that they quit entirely on their own, without a formal program or counseling. While some of the women also said that they stopped with the help of friends and that they switched to low tar and nicotine cigarettes to help themselves quit, clearly the vast majority, regardless of whether they quit early or later during pregnancy, attributed their behavior to their own initiatives.

Discussion

The potential effect of recall bias on the results of this study should be considered. Because of the survey design, a woman may have been asked to recall her smoking habits that occurred five or six years earlier. About 22 percent of the women in the sample delivered in 1980–81, 56 percent from 1982–84, and 22 percent in 1985–86. There was a decrease in the proportion of White women smokers between 1980 and 1985–86, similar to the decline observed in the NHIS data collected during those years.[18] Moreover, smoking history recall over a 10-year period was found to be quite reliable.[19] Thus, recall bias in the current study should not have a major effect on the conclusions.

Nearly all women in this sample received prenatal care and most smokers reported that they had been advised by a doctor to quit smoking. Those who did not quit were, in fact, more likely than quitters to report such advice (83 vs 57 percent); this apparent paradox probably reflects their longer opportunity to be given this advice on repeated prenatal visits. We cannot distinguish the role that counseling during prenatal care might have played in encouraging women to quit; it is possible that women who quit early did so in response to counseling that occurred at their first prenatal visit when they were told they were pregnant. Several previous studies have documented that the advice of a doctor or nurse can be very important in encouraging smokers to quit.[20] A variety of materials are available to health providers who want to provide smoking cessation help to their smoking patients.[21]

We found strong educational differentials in smoking prevalence and in quitting. This reinforces the conclusions of a recent study of smoking prevalence in the general population.[22] Between 1974 and 1985 smoking declined five

times faster among college graduates compared with those with less than a high school education.

Pregnant women appear to quit smoking at a greater rate than the general population. Based on data from the 1986 Adult Use of Tobacco Survey, an estimated 28 percent of persons 17 years of age and over who had smoked in the preceding 12 months quit smoking for at least one week during the year.[1] The proportion of White women who quit for at least a week while pregnant is higher—39 percent.

Relapse rates among women who quit smoking during pregnancy appear to be somewhat less than among quitters in the total population. In general, about 80 percent of smokers who quit resume smoking within a year. This is similar to the relapse rates for other drug dependencies.[23] In our study, 81 percent of White women who quit late in pregnancy also resumed within a year, but only 66 percent of those who quit early resumed smoking again within a year. Thus for some women, pregnancy appears to be an event that could be more likely to result in longer-term abstinence than smoking cessation for other reasons.

It is also noteworthy that women who quit smoking while pregnant resume smoking after delivery at a similar pace to quitters in the general population. In both instances, there is a precipitous rise in the proportion who resume smoking by three months followed by a relatively smaller increase by six months. The likelihood of resuming after six months is less than during the preceding months.[23] The underlying difference between these two groups, however, is that these pregnant women were abstinent during their pregnancy before they resumed smoking again.

However, the fact that relapse rates are high suggests that while the fetus's health is a strong influence on women's smoking habits, women may be less aware of the effect of passive smoke on the infant. Children of parents who smoked are more likely to have a variety of health problems such as respiratory illnesses than children of parents who do not smoke.[6–9] Education about the deleterious effects of infant and childhood exposure to passive smoke should be an essential part of comprehensive prenatal and postpartum care. Intervention programs for pregnant smokers should focus on assisting them to quit permanently.

Screening for *Chlamydia Trachomatis* in Adolescent Males: A Cost-Based Decision Analysis

ADRIENNE G. RANDOLPH, MD, AND A. EUGENE WASHINGTON, MD, MSc

Abstract: To evaluate the cost and benefits of screening tests for *Chlamydia trachomatis* in adolescent males, we developed a decision analysis model and compared the leukocyte esterase urine dipstick test with culture, with direct-smear fluorescent antibody (DFA), and with the option of no screening (no treatment). The leukocyte esterase test has the lowest average cost-per-cure ($51) compared with direct-smear fluorescent antibody ($192) and culture ($414). Compared with the DFA, we estimate that the leukocyte esterase test saves over $9,727 per cohort of 1,000 sexually active adolescent males screened. Sensitivity analyses show the leukocyte esterase test results in a lower cost-per-cure and lower overall costs (per cohort) than culture and direct-smear fluorescent antibody at any prevalence of *C. trachomatis* infection, and lower overall costs (per cohort) than no screening at prevalences above 21 percent. (*Am J Public Health* 1990; 80:545–550.)

Introduction

Infections caused by *Chlamydia trachomatis* are among the most prevalent and costly in the United States. Over four million chlamydial infections occur each year at a cost exceeding $1.5 billion dollars.[1,2] Adolescents have the highest rates of chlamydial infection and associated complications of any age group.[3–5] Considerable attention is now being focused on young women at risk for contracting *C. trachomatis* because of the dire reproductive consequences of a chlamydial infection. These include mucopurulent cervicitis, acute pelvic inflammatory disease, ectopic pregnancy, infertility, and maternal and infant infections during pregnancy and following delivery.[6–8]

Young men are equally at risk for a chlamydial infection. *C. trachomatis* causes approximately 50 percent of the reported cases of nongonococcal urethritis among males, and is also responsible for over 50 percent of cases of acute epididymitis in young men[8]; epididymitis is a painful, serious complication of chlamydial infection that could result in sterility. Moreover, infected adolescent males, particularly the 30 percent with asymptomatic chlamydial urethritis, represent the major source of *C. trachomatis* transmission to teenage females.[4,9]

Nevertheless, limited resources and limited availability of diagnostic tests have dictated the need to focus on screening females first. With newer, inexpensive and reliable tests now available, however, routine screening of males should be considered and evaluated. In this article, we evaluate the cost and benefits of the three commercially available screening methods for *C. trachomatis* in a population of adolescent males at risk for infection. We compare the leukocyte esterase urine dipstick test to urethral culture, to antigen detection* of a urethral smear, and with the option of not screening or treating.

Methods

Decision Analysis Model

We used a decision tree (Figure 1) to evaluate the possible outcomes associated with three screening tests for *C. trachomatis* in a population of adolescent males: 1) leukocyte esterase (LE) urine dipstick with a 1+ or 2+ reading on first catch urine; 2) urethral culture; and 3) antigen detection* (DFA) or a urethral smear. These were compared with the option of no screening (no treatment). Baseline probabilities used in our model were obtained from published data (Table 1). Our denominator for calculating baseline outcomes and costs is a cohort of 1,000 sexually active adolescent males.

Data and Assumptions

Chlamydia Prevalence (Node 1): We used 15 percent as the baseline prevalence to be conservative in estimating outcomes, but we also performed sensitivity analyses** to test the effect of using different prevalences on our conclusions.[4,9–14]

Sensitivity (Node 2) and Specificity (Node 3) of Screening Test: We used a conservative sensitivity estimate of 75 percent.[10,11] Since many false positive dipstick tests will be due to the presence of *N. gonorrhoeae*, for which at least 85 percent of strains are susceptible to tetracycline,[15] and has sequelae for uncured cases similar to that of *C. trachomatis*, we assumed a specificity of 85 percent based on results of screening only asymptomatic males.[11] Test sensitivity and test specificity for culture of *C. trachomatis* were assumed to be 90 percent and 99 percent, respectively.[16] For the DFA test we estimated the sensitivity to be 80 percent and the specificity to be 97 percent.[17,18] We performed a sensitivity analysis of the LE test through the range of probabilities in Table 1.

Follow Up (Node 4): When there is a delay between taking a test and the availability of results, some patients will be lost-to-follow-up. We used a loss-to-follow-up rate of 3 percent (range 3 to 10 percent) for the culture and direct-smear (DFA) test, because in most clinical settings results are not available for one to three days after obtaining a specimen. This follow-up rate is based on a high yield, cost-effective, field follow-up method of tracking males with positive chlamydial tests.[19] Results from the LE urine dipstick are

**Sensitivity analysis is the process of varying assumptions in a decision analysis.

TABLE 1—Probabilities Used in Decision Analysis

	Probability		
	Baseline %	Range %	Reference
Prevalence of chlamydia	15	5–35	4,9–14
Sensitivity of leukocyte esterase	75	65–85	10,11
Specificity of leukocyte esterase	85	75–95	10,11
Sensitivity of culture	90		16
Specificity of culture	99		16
Sensitivity of direct-smear fluorescent antibody	80		17,18
Specificity of direct-smear fluorescent antibody	97		17,18
Loss-to-follow-up rate	3	3–10	19
Compliance with treatment	65	65–95	20–22
Effectiveness of treatment	95		15,23
Spontaneous cure rate	5		8
Pelvic inflammatory disease rate (infected partners)	20	10–30	3,26,29
Probability of infecting a female	30	20–40	19

generally available immediately, therefore we assumed no loss-to-follow-up for this screening test.

Compliance (Node 5): We conservatively estimated the compliance to be 65 percent (range 65 to 95 percent) in this population based on studies that show: a compliance rate of 66 to 79 percent of men treated with a five-day course of doxycycline for *N. gonorrhoeae*,[20] and an overall compliance rate for pediatric populations of approximately 50 percent, with a range of 20 to 80 percent.[21,22] We assumed that noncompliers had failed treatment, and that only those with spontaneous cure (5 percent) were free of disease.

Efficacy of Treatment (Node 6): Cure rates for the tetracyclines in treatment of chlamydial urethritis in males range from 91 percent to 99 percent.[15,23] We used a cure rate of 95 percent for our base-line analysis, the mean rate from published reports. Theoretically, other drug regimens such as trimethaprim-sulfamethoxasole[15] could also be used with the cost estimates adjusted accordingly.

Spontaneous Cure Rate (Node 7): We assumed a spontaneous cure rate of 5 percent for infected males who did not receive treatment.[8]

Cost Estimates

This decision model used medical care costs as utilities (Table 2). Only direct costs were considered with charges used to approximate costs.

Screening Test: We surveyed several laboratories in the San Francisco Bay metropolitan area to derive an average cost of $0.50 for LE dipstick (including the cost of the urine container), $30 for culture, and $10 for DFA. The cost of collecting the tests, performing the LE urine dipstick in the office, and of packaging the DFA and culture and sending them to the laboratory was assessed as $10.

Follow-up and Loss-to-Follow-up: The cost of tracking down clients with positive cultures or positive DFA tests and arranging an office visit has been shown to be $10.67.[19] Since a fair amount of time can be spent attempting to track down

TABLE 2—Cost Assumptions Used in Decision Analysis

Leukocyte esterase urine dipstick	$ 0.50
Culture	30.00
Direct-smear fluorescent antibody	10.00
Test collection and processing	10.00
Follow-up	10.67
Loss-to-follow-up	10.67
Treatment (doxycycline hyclate)	10.00
Complications in untreated males	34.34
Infecting a female partner	366.72

persons lost to follow-up, a cost of $10.67 was included for all clients with positive cultures or DFAs lost to follow-up.

Treatment: The $10 cost of treatment includes the cost of medication and the pharmacy charge. The current bulk cost for a seven-day treatment course of doxycycline hyclate 100 mg PO bid is less than $2.[24] We added in an additional $8 charge for dispensing, storing, and ordering the medication.

Complications in Sex Partners: The average cost of infecting a female partner, including transmission to neonates, was $366.72 using the baseline PID rate of 20 percent (Appendix Table A). This estimate is based on the probabilities shown in Table 1, and costs per incident of medical care in Table 2, and published data on the probability of chlamydial complications in women and neonates and associated costs.[1,2,25,26] The Appendix provides details of these calculations. This cost was decreased to $195.38 per female by decreasing the pelvic inflammatory disease (PID) rate to 10 percent, and increased to $538.05 per female by increasing the PID rate to 30 percent. We assumed that the probability of a male infecting a female was 0.30.[19] However, this variable was also ranged from 0.20 to 0.40.

Complications in Males: The cost of return visits for symptomatic infections in untreated males was assessed to be $45 ($35 office visit plus $10 treatment) with a probability of occurrence of 75 percent. This means that only about 56 percent (1×.75×.75) of infected men will return, because 25 percent will be asymptomatic. The cost of outpatient treatment for epididymitis was assessed to be $50 with a probability of occurrence of 3.6 percent in untreated males.[2,8] The cost of inpatient treatment for epididymitis was calculated to be $1,836 with a probability of occurrence in 0.4 percent of untreated males.[2,8] This results in a total cost for complications per untreated male of $34.34.

Results

Cost Savings at Baseline Assumptions

When total medical costs and cost-per-cure are considered, screening with the LE test results in the greatest cost savings (Table 3). Screening with the LE test costs 12 percent as much as culture and 27 percent as much as the DFA. The average cost-per-cure of a chlamydial infection is $51 when the LE test is used compared with $414 per cure with culture and $192 per cure with the DFA. This cost-per-cure is unchanged by decreasing the cohort of adolescent males screened to 100. Overall, screening with the LE test will save over $28,459 per 1,000 adolescent males at risk for *C. trachomatis* infection compared with culture and $9,727 compared with the DFA.

TABLE 3—Overall Cost and Outcomes for Different Screening Strategies*

Screening Strategy	Cost		Health Outcome	
	Total	Per Cure**	Cure (%)	Unnecessary Rx
Leukocyte esterase	$23,944	$ 51	73 (49%)	219
Culture	52,403	414	84 (56%)	15
Direct-smear fluorescent antibody	33,671	192	76 (51%)	44
No screening	20,571	—	8 (5%)	0

*Per cohort of 1,000 sexually active adolescent males screened for *C. trachomatis* infection.

**Cost-per-cure = (total costs screening method minus total costs no screening)/(total cures screening strategy minus total cures no screening).

* = Prevalance = 35%; LE Sensitivity 85%/Specificity 95%; PID Rate 30%; Infected Partner Rate 40%; Compliance 95%

** = Prevalence = 5%; LE Sensitivity 65%/Specificity 75%; PID Rate 10%; Infected Partner Rate 20%; Compliance 65%.

Health Outcomes at Baseline Assumptions

Screening with culture results in the highest percent cure rate (56 percent) per 1,000 adolescent males (Table 3). Screening with the DFA results in the second highest percent cure rate (51 percent), while the LE results in the lowest percent cure rate of the three tests (49 percent). The strategy of not screening results in a 44 to 51 percent lower cure rate than any of the three screening options. Fewer patients will be treated unnecessarily with culture and direct-smear (DFA) screening compared with the LE test (see Table 3).

Sensitivity Analysis and Break-Even Prevalence

Sensitivity analyses were performed on seven variables (Table 4). Because the LE test and the DFA appear to be the more practical options for screening, culture was not included in the sensitivity analysis.

At base-line assumptions, the disease prevalence which leads the LE test to break even when compared with the cost of not screening is 21 percent. Above this prevalence, the LE test always costs less than not screening. The break even prevalence for the DFA is 41 percent. Using base-line assumptions, the LE test will be less costly than the DFA at any prevalence. As the prevalence is lowered to 5 percent, the cost/cure for the LE rises to $415 and for the DFA to $795.

Increasing the sensitivity/specificity of the LE test will, as expected, make the LE test even more cost-effective (lower cost-per-cure, and/or lower total costs and higher or equivalent cure rate) compared with the DFA. Even at the lowest sensitivity/specificity for the LE, the cost-per-cure is still only 48 percent of the cost of the DFA.

Increasing the PID rate in infected partners to 30 percent results in the LE breaking even compared to not screening. The DFA would still cost $140 per cure. Decreasing the PID rate to 10 percent results in the LE costing $103 per cure with the DFA costing $243 per cure. Increasing the probability of infecting a female to 40 percent results in the LE test costing $14 per cure and the DFA costing $155 per cure. Decreasing the probability of infecting a female partner to 20 percent

results in the LE costing $88 per cure and the DFA costing $229 per cure.

If the loss-to-follow-up for culture and the DFA is raised to 10 percent, the percent cure rate for culture is still the highest (53 percent), with the LE next (49 percent) and the DFA the least effective (47 percent cure). The cost per cure for the DFA rises to $216 compared to $51 for the LE. If the loss-to-follow-up rate is 7 percent, the percent cure rate for the LE is equal to the DFA.

If the compliance rate were increased to 95 percent with all other variables at base-line, the LE would save $11 per cure (cost-per-cure = $51 at 65 percent compliance) and the cost-per-cure for the DFA would drop to $86 (from $192 at 65 percent compliance).

If the "best case" scenario for use of screening tests is applied (high sensitivity/specificity of tests, high prevalence of disease, high PID rate in infected partners, high probability of infecting a partner) the LE saves $195 per cure, the DFA saves $137 per cure, and culture saves $6 per cure. If the "worst case" scenario for use of screening tests is applied (low sensitivity/specificity of tests, low prevalence of disease, low PID rate in infected partners, low probability of infecting a partner) then the LE costs $619 per cure and the DFA costs $866 per cure.

Discussion

Our analysis indicates that the leukocyte esterase (LE) urine dipstick test, when used to screen for *Chlamydia trachomatis* in a population of sexually active adolescent males results in greater cost savings than screening with either DFA or culture. This finding is true throughout the range of sensitivity analyses for seven separate variables. Moreover, screening with the LE urine dipstick test in this population can result in an equivalent number of cures if the loss-to-follow-up rate for the DFA test is greater than 6 percent. These findings clearly underscore the effectiveness and substantial benefits of the LE test and support its use in this at risk population that is currently not routinely screened.

In populations where contacting patients with test results and treatment recommendations is not problematic and the prevalence of *C. trachomatis* is very high, the cost-per-cure for the DFA is substantially reduced. The higher costs associated with use of the DFA over the LE must be balanced against the high incidence of unnecessary treatment resulting from the lower specificity of the LE test. Since the LE false positive rate was established using cultures which probably have <90 percent sensitivity,[17] the LE may be detecting infections which would be missed by DFA or culture. We also recognize that some false positive LE dipstick tests in adolescent males are due to the presence of *N. gonorrhoeae* so that treatment unnecessary for the eradication of chlamydia would ultimately be of benefit. We did not attempt to place a value (or utility) on the outcome of unnecessary treatment. While the morbidity associated with tetracycline therapy in males is certainly minimal, the psychosocial consequences of inappropriate diagnosis and unnecessary treatment could conceivably impose a heavy burden on these young males and their sex partners.

Recognizing that the specificity of the LE test is much lower than that estimated for the DFA, and that precise identification of an infecting organism has potential therapeutic and health education value, have led practitioners to advocate the use of the LE as a screening test leading to further testing with culture or DFA.[10,11] Although use of this strategy would decrease the number of unnecessary treatments, the number of cured chlamydial infections would be lowered due to the combined false negative rates of both tests. Overall costs and cost-per-cure would be increased when compared with use of the LE alone. In populations where the prevalence of chlamydial infection is high and few patients are lost to follow-up, the cost-per-cure for the DFA may be acceptable enough for use as a screening test. In these populations, the higher expense for the DFA compared with the LE may be offset by the decreased number of unnecessary treated patients. Use of the LE as a predictor for further testing may be most beneficial in populations with a low prevalence of chlamydial infection and a high rate of follow-up, since the low specificity of the LE has the greatest relative impact in terms of unnecessary treatments at low disease prevalences.

Compliance with treatment is an important variable that significantly impacts the total costs and cost-per-cure for each screening strategy. If compliance with treatment could be increased to 95 percent, screening with the LE would save money over no screening. Similarly, increasing the compliance with treatment significantly reduces the cost-per-cure for the DFA and, if the follow-up rate was also high, some practitioners may find the cost-per-cure for the DFA to be in an acceptable range even at moderately low prevalences.

Our analysis focused on screening only for *C. trachomatis* with the LE test when the studies we cite[10,11] which determined the effectiveness of the LE test actually addressed both *C. trachomatis* and *N. gonorrhoeae* in asymptomatic adolescent males. The sensitivities and 100 percent specificities found in these studies were based on confirmed infection with either *C. trachomatis* or *N. gonorrhoeae*, or both. Since the sensitivity was 100 percent in one study, and the specificity was 100 percent in the other, our conservative sensitivity and specificity assumptions of 75 percent and 85 percent for the LE should absorb the effect of *N. gonorrhoeae*.

As with the LE, the sensitivity and specificity of the DFA in this population of all sexually active adolescent males are unknown. The DFA test was evaluated in men with symptoms or signs of urethritis and has not been evaluated in low-risk, asymptomatic men.[17] The sensitivity and specificity may be lower in adolescent male asymptomatic carriers. The LE test is aimed at detecting the pool of asymptomatic adolescent males who may be the main transmitters of infection to adolescent females. Sensitivity and specificity of the DFA test are also highly dependent on the skill and expertise of the microscopist interpreting the slide.[17] In laboratories with inexperienced technicians, the number of false-positive and false-negative results will bring the sensitivity and specificity toward the lower end of the spectrum.

We did not include in our analysis the strategy of empiric treatment of all sexually active adolescent males attending a clinic or physician's office. One study of patients at a sexually transmitted disease (STD) clinic[27] found this strategy to be the most cost-effective when compared with the strategies of culturing all patients and only treating those with positive results; empirically treating patients at high risk and culturing those at low risk; and empirically treating patients at high risk and neither culturing nor treating those at low risk. We initially evaluated this strategy and found it resulted in cost-per-cure of $(-)14, with 95 cures, 55 no cures, and 850 unnecessary treatments per 1,000 adolescent males. However, we elected not to present the empiric treatment data in

our comparative decision analyses because we agree with other investigators that this is not a feasible health policy option.[27] Not only would there be no basis for determining frequency of treatment, except perhaps level of sexual activity, but deciding about treatment of sex partners would also prove difficult. Furthermore, indiscriminate use of tetracycline could adversely affect antimicrobial sensitivity patterns, leading to resistant *N. gonorrhoeae* and possibly *C. trachomatis* as well.

The major costs associated with adolescent male chlamydial infection result from the costs associated with infecting a female partner. Although we have data to support the incidence of sequelae from chlamydial infection in females, and the associated costs resulting from the medical management of these sequelae, there are no firm data on the transmission rate from males to their female sexual partners. Recognizing that the transmission might have been from female partner to the adolescent male, that some adolescent females might already be infected with the same serovar of *C. trachomatis* from another partner and cannot be reinfected, and that the transmission rate is probably lower than 100 percent, we conservatively assumed that an infected male has a 0.30 change of infecting a female. Studies have shown that 30 percent of reported female partners of males with urethritis will be infected with *C. trachomatis*.[19] Since many adolescents have multiple sexual partners and may not report all of these partners, our sensitivity analysis which ranges the probability of infecting a female from 0.20 to 0.40 should cover any inaccuracy surrounding this variable.

These considerations notwithstanding, our analysis provides reasonable estimates of the risks, benefits, and costs of screening for *C. trachomatis* with the LE urine dipstick test compared with culture, DFA and not screening. Where imprecision exists, we believe it is in the direction of underestimating benefits and cost savings. For example, we did not include indirect costs, which are about equal to direct costs[2,26]; adding them would further increase the cost saving and enhance the cost-effectiveness of the LE test. Neither did we include the noneconomic benefits. These include the prevention of adverse psychosocial effects in males at risk for epididymitis and in their female partners who might later suffer from PID, ectopic pregnancy (with its resultant fetal loss and risk of maternal mortality), or infertility.

One other benefit not included in our analysis is the treatment of coexisting *N. gonorrhoeae* in adolescents diagnosed with *C. trachomatis* by the LE test. While data are not available on this coinfection rate, the rate of coexisting *C. trachomatis* in patients diagnosed with *N. gonorrhoeae* ranges from 15 to 30 percent in males and 25 to 50 percent in females.[8,13,28] Assuming the rate of coexisting *N. gonorrhoeae* in patients diagnosed with *C. trachomatis* is similar, then a significant number of gonococcal infections will be treated along with the chlamydial infection, because a seven-day course of doxycycline hyclate (100 mg PO bid) will eradicate at least 85 percent of infections due to *N. gonorrhoeae* since the highest reported rate of tetracycline resistent *N. gonorrhoeae* is 15 percent.[15,20] Importantly, treatment of these asymptomatic gonococcal infections would prevent transmission to susceptible females and subsequent adverse reproductive consequences. This would lead to even greater cost savings with the LE test compared to other screening methods and to not screening than what was calculated in our study.

The added benefits of the LE in detecting *N. gonorrhoeae* leads to combined *C. trachomatis*/*N. gonorrhoeae* treatment recommendations.[29,30] Not only does there appear to be an increasing treatment failure rate among patients with *N. gonorrhoeae* taking tetracycline exclusively,[31] but also the expected compliance with a seven-day treatment course is only 65 percent. Compliance with *N. gonorrhoeae* treatment would be raised to 100 percent if LE dipstick-positive adolescent males were given 250 mg ceftriaxone intramuscularly once or a one time oral dose of 3.5 g ampicillin/1 g probenicid before leaving the physician's office, and then given their seven-day course of doxycycline hyclate 100 mg PO bid to eradicate 95 percent of *C. trachomatis* in those who are compliant with treatment. Tracking of penicillin-resistant *N. gonorrhoeae* could be accomplished by culturing all males with a discharge, dysuria, history of exposure to a sexually transmitted infection, and/or a positive LE urine dipstick test for *N. gonorrhoeae*.

Although there are several studies that compare the costs and benefits of screening programs for *C. trachomatis* in females,[27,32,33] this is the first study that directly compares the costs and benefits of screening in adolescent males. This population represents a key link in the chain of transmission of chlamydial disease, yet routine screening of this group is not widely practiced. Since the cost-per-cure is unaffected by the size of the cohort, our analysis provides a model that practitioners can apply once they outline the characteristics of their cohort. To prevent further transmission and minimize the risk that an infected individual will have adverse consequences, clinicians should assess the prevalence and loss-to-follow-up rate in their populations, and consider using the LE urine dipstick test or the DFA, alone or in combination, for screening sexually active adolescent males to detect *Chlamydia trachomatis* infection.

APPENDIX

Cost-effectiveness Calculations

The cost of infecting a single female partner and the costs of potential neonatal transmission and its probability are calculated as shown in Appendix Table A. Appendix Table B shows the cost per *C. trachomatis* infected male assuming that 30 percent (range 20 to 40 percent) of female partners exposed by the male would become infected and have the costs and risks in Table A. We did not include potential male-to-male transmission. We assumed that 20 percent of female partners would present for treatment.[19] The cost of treating infected female partners included two outpatient visits, one DFA test, a seven-day course of doxycycline and treatment of the vaginitis expected in 10 percent of treated partners from the antibiotic therapy. Given the 20 percent false negative rate for the DFA,[17,18] we assumed that 16 percent of infected female partners would be treated with complete eradication of *C. trachomatis* and prevention of any sequelae. For the 84 percent of untreated female partners, we expected a 20 percent PID rate (range 10 to 30 percent) with the costs of treating the PID and it's sequelae listed in Table A. We predicted a 5 percent birth rate and estimated a 20 percent chlamydial conjunctivitis rate and a 10 percent chlamydial pneumonia rate in neonates born to *C. trachomatis* infected mothers. The cost of complications in males infected with chlamydia is combined with the cost of infecting female partners and the costs of potential neonatal transmission to result in an average cost per *C. trachomatis* infected male of $144.36 (Table B). The number of infected males was calculated by multiplying probability estimates down each pathway of the model and considering all those ending with "no cure" as infected and all those ending with efficacious treatment or spontaneous cures as "cured." Total costs were calculated by multiplying all "no cure" totals with the cost of infected males ($144.36) and adding this product to the following: 1) the cost of each test times the cohort; 2) the cost of follow-up and loss-to-follow-up times their probabilities of occurrence; plus 3) the cost of treatment and its probability of occurrence. This total cost calculation was divided by the number "cured" to obtain the cost-per-cure. The number unnecessarily treated equals the number of false positive tests. We used a microcomputer spreadsheet program to model the number of cures and costs.

APPENDIX TABLE A—Cost of Infecting Female Partners with *C. trachomatis* and Transmission to Neonates

	Cost	Probability	Reference
Infected female partners			
Rx fluorescent antibody		.20	
Direct-smear	$ 8	1.00	
Two outpatient visits	70	1.00	25
Vaginitis (complication Rx)	30	.10	26,27,29

Information on Tar and Nicotine Yields on Cigarette Packages

RONALD M. DAVIS, MD, PATRICIA HEALY, AND SUSAN A. HAWK, EDM, MS

Abstract: We examined information on tar and nicotine yields on the packages of 160 cigarette brands, 58 percent of the 275 brands for which tar and nicotine yields were listed in a recent Federal Trade Commission report. The tar yield was indicated on 14 percent, the nicotine yield was indicated on 11 percent. As tar yield increased among brands, the yield was progressively less likely to be shown on the package and was not disclosed on the package of any cigarette yielding 11 mg or more of tar. (*Am J Public Health* 1990; 80:551—553.)

Introduction

Since 1971, all major cigarette manufacturers have voluntarily disclosed the tar and nicotine yields of cigarette brands in advertisements.[1] The cigarette industry agreed to "voluntary" disclosure after the US Federal Trade Commission (FTC) had proposed a regulation that would have required such disclosure.[2] This agreement does not apply to cigarette packages.

The tar and nicotine yields listed in cigarette ads have been obtained by machine smoking of cigarettes under standardized laboratory conditions using an FTC method developed in the 1960s.[3] Through early 1987, the FTC conducted tar and nicotine measurements in its in-house laboratory; currently, the Tobacco Institute Testing Laboratory performs tar and nicotine measurements using the FTC's standard method. The Institute provides these test results to the FTC which, in turn, makes the information available in a public report.[4]

In 1981, the Secretary of Health and Human Services recommended that:

> " . . . manufacturers should list yields of 'tar', nicotine and other hazardous components on their packages and in their advertising with appropriate explanatory information on the health significance of these measurements. This would be a minimum first step in giving cigarette consumers full and adequate information about the products they are buying."[5]

Seven years after that recommendation was made, we conducted a study to examine the types of information related to tar and nicotine yields that are provided on cigarette packages.

Methods

In May of 1988, we visited eight retail stores that sell cigarettes in Montgomery County, Maryland to find as many different cigarette brands as possible. We found 160 (58 percent) of the 275 brands listed in a 1988 FTC report on tar, nicotine, and carbon monoxide yields of domestic cigarettes.[4] (The 275 brands include 272 in the report's primary listing, plus three varieties of Barclay cigarettes for which tar and nicotine yields were provided in the text.) These 160 brands accounted for approximately 78 percent of the domestic cigarette market in the second quarter of 1988.[6]

Many of the 160 brands were "extensions" of the same primary brand name but differed in cigarette length, the type of package (soft or hard pack), the number of cigarettes per package (20 or 25), the presence or absence of a filter, or the presence or absence of metholation. All of these variables (including type of package) may be associated with differences in tar and nicotine yield.[4,7]

For each brand, we examined the package for any information relating to tar and nicotine yields, including quantitative measurements (mg per cigarette) and qualitative descriptions (e.g., "light," "low-tar," "99% tar free"). Because tar and nicotine yields in cigarette brands are highly correlated (high-tar brands tend to have high nicotine yield, and low-tar brands tend to have low nicotine yield),[4] we analyzed package labeling patterns only with respect to tar yields.

For six brands, the tar yield indicated on the package was 1–2 mg higher or lower than the yield listed in the FTC report. In these cases, we used the yield indicated on the package in our analysis of package labeling patterns.

Results

Package Disclosure of Tar and Nicotine Yields

The tar yield was indicated on the package of 23 brands (14 percent). For 17 (74 percent) of the 23 brands, the nicotine yield was also indicated. In no case was the nicotine yield shown without the tar yield. The 23 brands fell within six brand "families" produced by five different manufacturers: seven Carlton varieties (American Brands); seven Merit varieties (Philip Morris Company); three Now varieties (RJR/Nabisco); three Barclay varieties (Brown & Williamson Corp.); two Triumph varieties (Loews Corp.); and one Benson & Hedges variety (Philip Morris). The 23 brands accounted for approximately 5 percent of the domestic cigarette market in the second quarter of 1988,[6] or about 6 percent of the combined market share of the 160 brands in our sample (78 percent).

Table 1 shows the proportion of brands whose packages disclosed tar yield within the six tar-yield categories used by the FTC in analyzing cigarette sales and advertising expenditures.[8] As tar yield increased among brands, the package was progressively less likely to show the yield. The tar yield was disclosed for all 11 brands yielding 3 mg or less of tar but not for any of the brands yielding 11 mg or more. When the six tar-yield categories shown in Table 1 are collapsed into four categories to allow use of the chi-square test for trend, the trend is statistically significant ($p < 0.001$, two-tailed).

Package Label Messages

Table 2 shows the frequency of use of words and phrases on cigarette packages that indicate or suggest a low-tar/

TABLE 1—Proportion of Cigarette Brands That Disclose Tar Yield on Packages, among a Sample of 160 Brands (stratified by tar yield), United States, May 1988

Tar Yield* (mg/cigarette)	Total Brands	Brands with Tar Yield on Package	
		N	%
≤ 3	11	11	100
4–6	19	6	32
7–9	29	5	17
10–12	46	1	2
13–15	23	0	0
≥ 16	32	0	0
Total	160	23	14

*Source of information on tar yields of cigarette brands is the Federal Trade Commission.[4]

low-nicotine yield, stratified by tar yield. Five brands claimed to have the lowest yield. Two varieties of Carlton cigarettes, each having a tar yield of 1 mg, claimed that "Carlton is lowest." Three varieties of Now cigarettes, having tar yields of 1 mg, 2 mg, and 3 mg, claimed that "Now is lowest." Three varieties of Barclay cigarettes, ranging from 3 to 5 mg of tar, were said to be "99% tar free."

The phrases "ultra low tar" and "ultra lights" were used almost exclusively for brands yielding 7 mg or less of tar. The terms "low tar" and "lights" were generally used for brands yielding 15 mg or less of tar, conforming with the FTC's usual definition of low-tar cigarettes.[9] However, three brands with tar yields of 16–18 mg were called "lights" (Doral Lights king-size soft-pack, Richland Lights 100's soft-pack, and Richland Lights Menthol king-size soft-pack). One "ultra low tar" brand (Merit Menthol 100's soft pack) had a tar yield of 10 mg, which is higher than that of some brands labeled as merely "low tar." One brand (Lucky Strike Unfiltered Lights) had the phrase "only 9 mg tar" on the package.

TABLE 2—Frequency of Use of Words and Phrases on Cigarette Packages That Indicate or Suggest a Low-Tar/Low-Nicotine Yield, among a Sample of 160 Brands (stratified by tar yield), United States, May 1988

Tar Yield* (mg/cigarette)	Wording	Brands	
		N**	%
≤ 6	Ultra low tar	16	53
(N = 30)	Ultra lights	13	43
	Lowest	5	17
	99% tar free	3	10
	Ultra low	2	7
	Smooth	2	7
7–12	Light/Lights	49	65
(N = 75)	Low tar	29	39
	Lowered tar & nicotine	5	7
	Ultra low tar	3	4
	Mild/Milds	3	4
	Low nicotine	2	3
	Smooth	2	3
	Ultra lights	1	1
	Recessed filter	1	1
	Famous Micronite II filter	1	2
≥ 13	Light/Lights	8	15
(N = 55)	Smooth	6	11
	Low tar	5	9
	Mellow	2	4
	Activated charcoal filter	2	4
	Famous Micronite II filter	1	2
	Mild	1	2

*Source of information on tar yields of cigarette brands is the Federal Trade Commission.[4]

**Within a particular tar-yield category, the sum may exceed the total because some package labels used more than one descriptive term.

Several words or phrases that may suggest a low-tar yield are used on packages, including "smooth," "mild," "mellow," and references to special filters (Table 2). One filter was described in detail on the package: "Lark Lights filter has two outer 'tar' and nicotine filters, plus an inner chamber of tiny charcoal granules specially treated to smooth the taste in a way no other filter can." The term "full flavor," often used by cigarette companies as a euphemism for high tar, appeared on the package of three brands yielding 14–17 mg of tar (Cambridge and Doral varieties).

Discussion

Although several studies have shown that those who smoke lower tar cigarettes have a reduced risk of lung cancer,[5,10,11] many concerns have been expressed about low-yield cigarettes.[12,13] First, because the cigarettes are less harsh, they may facilitate experimentation with and initiation of smoking among children and adolescents. Second, smokers who switch to lower yield brands often change their smoking behavior to compensate for reduced nicotine delivery (e.g., by increasing daily cigarette consumption; by increasing the depth, duration, or frequency of puffs; or by smoking cigarettes to a shorter butt length).[14–17] These compensatory changes may, in some smokers, increase the total intake of tobacco smoke constituents. Third, the use of flavoring additives is thought to be more common in low-tar brands to compensate for reduced "taste." These additives and their products of combustion may pose additional health risks to smokers. Fourth, those who smoke lower yield cigarettes may consider them to be safe or less hazardous, and may therefore be less motivated to quit.[18] Fifth, there is little or no evidence that low-yield cigarettes reduce the risk of cancers other than lung, of cardiovascular disease, of chronic obstructive pulmonary disease, or of fetal damage when smoked during pregnancy.[5,13,19]

Consumers have received mixed messages about the advisability of switching to low-tar cigarettes. For example, widespread publicity in the media has followed the publication of articles reporting "benefits" of low-yield cigarettes.[20] These reports have been buttressed by cigarette advertising claims implying that low-tar cigarettes are less hazardous or safe.[18] On the other hand, articles reporting no "benefits" have also received substantial publicity.[19]

Consumers' ability to sort out and act on these disparate messages is complicated by the fact that package information on tar and nicotine is provided selectively and is ambiguous or inconsistent at times. Among the 160 brands included in our study, the tar yield was not disclosed for any brand yielding 11 mg or more of tar. (The sales-weighted average tar yield was 13 mg in 1987.[21]) Five different brands claimed to be "lowest," even though the tar yield of one (3 mg) was three times the tar yield of another (1 mg). One "ultra low tar" brand had a tar yield higher than that of several "low tar" brands. Three brands with tar yields ranging from 3 to 5 mg claimed to be "99% tar free," an ambiguous term which suggests the brands are virtually free of tar.

Requiring disclosure of tar and nicotine yields on all cigarette packages would eliminate the selective manner by which cigarette companies now provide this information. Uniform disclosure on packages would also make these figures more accessible than those currently provided on

cigarette advertisements. A standard coding system should be developed to define tar-yield categories using easily understood terms (e.g., low tar, medium tar, high tar). The appropriate designation could be required on each package and advertisement. Such a coding system is used in the United Kingdom for cigarette advertisements.[22] In the United States, no official government coding system exists for tar-yield terminology, and no industry standard apparently exists (Judith P. Wilkenfeld, Federal Trade Commission, oral communication, July 6, 1989).

Chapman, *et al*,[22] have suggested that retailers be required to display at the point of sale a table showing the yields of all brands (from lowest to highest yields). According to these authors, the state of South Australia has adopted a law implementing this recommendation.

Above all, mechanisms should be developed to warn consumers that any health benefits of switching to lower tar brands are minimal when compared with the benefits of quitting and are offset by smoking more cigarettes per day, puffing more frequently, etc. Warnings could be required, for instance, on package inserts, in advertisements, and at the point of sale. According to the 1986 Adult Use of Tobacco Survey, 21 percent of smokers (approximately 10 million Americans) believe that the kind of cigarettes they smoke are less hazardous than other cigarettes.[21] Many of these smokers might quit if they understood that any benefits of switching to low-yield cigarettes pale in comparison to the benefits of quitting.

Comparative Evaluation of American Cancer Society and American Lung Association Smoking Cessation Clinics

HARRY A. LANDO, PHD, PAUL G. MCGOVERN, PHD, FRANCISCO X. BARRIOS, PHD, AND BRUCE D. ETRINGER, PHD

Abstract: We compared the effectiveness of American Cancer Society, *FreshStart*, American Lung Association, *Freedom from Smoking*, and laboratory clinic methods in subjects (N = 1041) from three communities. Three-month follow-up results favored the laboratory method over the two public service approaches on both a prevalence and a sustained abstinence measure. At one-year follow-up, treatment effects for smoking prevalence were no longer significant. However, sustained abstinence results at one-year remained highly significant and favored the more intensive laboratory and *Freedom from Smoking* clinics over the *FreshStart* method. *FreshStart* fared less well than the other interventions both in producing initial quit attempts and in sustaining abstinence among initial quitters. It should be noted, however, that *FreshStart* requires considerably less facilitator contact than do the other approaches. Unexpected outcome effects occurred for treatment location. Future clinic programs should include a specific target date for quitting and should place more emphasis upon recycling participants who fail to sustain abstinence. (*Am J Public Health* 1990; 80:554–559.)

Introduction

Public service programs have been developed to assist chronic smokers to quit. Characteristics common to most of these programs include not only the use of behavioral principles, but also a focus on multiple program components, increasing emphasis on maintenance and relapse prevention, and a heightened appreciation of variables such as cognitive processes and social support.[1] As smoking cessation programs have become relatively more sophisticated, there has also been an increased awareness of the need for more cost-effective delivery methods.[2] Among the most widely offered public service programs are smoking cessation clinics developed by the American Cancer Society and the American Lung Association. Despite their widespread use, no evaluations of the effectiveness of these clinics have appeared to date in the literature.

The present study undertook a comparative evaluation of the American Cancer Society (ACS) *FreshStart* and American Lung Association (ALA) *Freedom from Smoking* clinic methods. These methods were assessed in a context that also included a laboratory-derived clinic approach.[3,4] The laboratory method was included to allow not only assessment of the effectiveness of the two public service clinics themselves, but of their effectiveness relative to that of a method systematically derived from a paradigmatic program of research[5] which has been systematically disseminated in community settings as part of a program of technology transfer. Costs have been kept to a minimum through the use of donated facilities and volunteer group leaders who receive only nominal fees.[6]

Methods

Subjects

Subjects were 1,041 smokers (57.2 percent women) who responded to newspaper advertisements announcing the availability of free smoking cessation clinics. The clinics were described as being part of a federally funded project. Subjects were recruited from three Iowa locations: Des Moines (N = 743), Iowa City (N = 173), and Waterloo-Cedar Falls (N = 125). Three study locations were used to ensure adequate subject enrollment and to allow a test of the major study hypotheses. The investigator in charge of administering treatment in Waterloo-Cedar Falls left after the first year of the study and recruitment efforts in the area were discontinued at that point.

Facilitators

Facilitators were 10 women and five men specifically recruited and trained to administer intervention for purposes of the current study. Although specific information on facilitator characteristics is not available, group leaders in Des Moines were older, ranging in age between 35 and 50, and most had previous experience in conducting group programs. In contrast, facilitators in Waterloo and Iowa City consisted primarily of undergraduate and graduate students less than 30 years old. Efforts were made to see that each facilitator conducted all three interventions. This was not always possible, however. It should be emphasized that we have no evidence of a facilitator effect upon treatment outcome.

All facilitators were formally trained in all three methods: the American Cancer Society *FreshStart* program, the American Lung Association *Freedom from Smoking* clinics, and the Lando laboratory derived approach. *FreshStart* training consisted of a four-hour program provided by the American Cancer Society. The smoking intervention coordinator for the American Lung Association of Iowa provided training in the *Freedom from Smoking* method. Project staff provided training in the Lando method. Formal instruction in the American Lung Association and Lando clinic procedures required approximately six to eight hours. Facilitators were provided copies of detailed treatment manuals for all three clinic approaches.

Facilitators were informed that the study was intended to assess the relative effectiveness of different methods, that it was unclear whether any method would prove superior to the others, and that a major purpose of the study was to determine which methods might be more effective for different people. Emphasis was placed upon the point that a critical overriding study goal was to assist as many people as possible to quit across all conditions. Every effort was made to minimize bias on the part of group leaders. Facilitators were recruited from each of the communities and individuals were employed who had no prior identification with any of

the programs. Strong emphasis was placed upon the need to conduct procedures exactly as described in the respective protocols.

Experimental Design

Subjects were randomly assigned to one of the three methods as a function of orientation sessions attended. Subjects were also informed that the study was comparing different methods and that while each of the methods was effective, the investigators believed that a particular method might be more effective for certain types of smokers. Treatment was offered free of charge.

Assigning all individuals attending a given orientation session to a single method minimized problems of self-selection to treatment. This was deemed important enough to outweigh any limitations arising from having different units of randomization and analysis. Only very general information that could apply to any of the three methods (e.g., small group format and a varying number of sessions) was released prior to the orientation. Friends and relatives who came together to orientation sessions were ensured the same treatment condition. A total of 70 orientation sessions were held and 97 treatment groups were eventually formed in the three intervention sites.

Preintervention Assessment

Subjects completed a brief demographic and smoking history questionnaire as well as an informed consent statement at the initial orientation session and provided the names and telephone numbers of three informants who could assist in locating them for purposes of follow-up data collection.

All subjects were informed that the programs would teach them skills to actively confront urges to smoke and enable them not only to stop smoking, but to remain nonsmokers. They were asked to verbalize a commitment to quitting that was intrinsic rather than a product of coercion from others. Emphasis was placed upon the premise that smoking is a learned habit and that it can be unlearned as well.

Attendance records allowed an indication of attrition *before* the fact (e.g., differential dropout subsequent to the orientation sessions as a function of anticipated treatment procedures). Details of the different interventions are contained in the Appendix.

Follow-up Data

A brief smoking status questionnaire was mailed to subjects at three-month, six-month, and 12-month follow-up intervals. Subjects who failed to respond to mailed questionnaires were contacted by telephone. Point prevalence was defined as complete abstinence from tobacco products on the day in question. Sustained abstinence was defined as the absence of relapse. Permitted slips were distinguished from relapses following guidelines recommended by the National Heart, Lung, and Blood Institute National Working Conference on Smoking Relapse[7] (a relapse was defined as seven consecutive days of smoking at least one puff per day). We specified an additional definition of relapse as seven consecutive slips within three months. Data were collected on whether subjects had made a quit attempt during the clinic they attended. A quit attempt was defined as at least 24 hours of continuous tobacco abstinence.[7]

Eighty subjects who claimed sustained abstinence through one-year follow-up (43.0 percent of the total claiming sustained abstinence) were asked to submit saliva samples about one month after their one-year follow-up had been completed. Saliva samples were collected in subjects' homes. All samples were analyzed for thiocyanate. Samples with borderline values (80–100 ng/ml) or higher (which appeared to contradict self-reported abstinence) were subsequently analyzed for cotinine (smoking was defined as a value of greater than 15 ng/ml). In the case of subjects who refused to submit to saliva testing, informants were telephoned and queried concerning the subjects' smoking status.

Results

Subject Characteristics

The average age of subjects was 42.4 years. Mean baseline cigarette consumption was 28.8 per day and the average number of years smoking was 23.6. Subjects had initiated a mean of 3.8 prior quit attempts with the longest abstinence period averaging 7.7 months. In an open-ended question asking about reasons for attempting to quit, 86 percent of subjects listed health concerns as one reason for quitting (Table 1).

Multivariate analysis of variance, performed to identify location differences, indicated that the Iowa City sample was on average 6.9 years younger and smoked 4.4 cigarettes less than their counterparts in the other two communities. Clinic size (i.e., the number of participants per clinic) was also considerably smaller in Iowa City.

Response Rates at Follow-Up

There was a 93.8 percent response rate at one-year follow-up. Response rates at three-month and six-month follow-ups were 98.2 percent and 93.0 percent, respectively. Forty-two people were not successfully contacted, 15 were lost to follow-up, five refused the follow-up interview, and three died. Those not reached, lost to follow-up, and refusers

*The median is reported for this variable because of the substantial skewness of responses.

were counted as smokers for purposes of data analysis. There were no differences between the treatment groups or locations in attrition rates at one-year.

Return to Treatment

For 62 of 70 informational meetings, data were available on the number attending the meeting as well as the number who returned to participate in treatment. A weighted least squares ANOVA indicated that the proportion returning was not a significant function of the treatment being offered.

Group size did not differ significantly as a function of the intervention method. Mean group sizes were 10.0, 11.7, and 10.5 for the ACS, ALA, and Lando methods, respectively.

Abstinence

The effects of method and location (and their interaction) on abstinence outcome were evaluated using logit analysis.[8] Lack of independence of outcome within treatment groups was expected due to individuals receiving treatment together in groups and having correlated outcomes, and related individuals (e.g., spouses) entering the same treatment group. A group effect was observed on one-year abstinence prevalence after method and location effects were taken into account ($\chi^2(92) = 123.32$, $p = .016$). Thus, an estimate of the design effect[9] due to clustering was computed (= 1.469), and the original chi-square test statistics were divided by the design effect to correct for this within group dependence.[10] Corrected chi-square statistics and confidence intervals are reported below.

Location effects did not interact with those due to treatment classification in any of the analyses reported. Also there were neither facilitator nor sex of subject effects on abstinence outcome.

Abstinence outcomes are illustrated in Figure 1; mean levels are presented in Table 2. While point prevalence differences are no longer statistically significant after the three-month follow-up interval, sustained abstinence differences are significant at all follow-up points. The ACS *FreshStart* program fared most poorly, and the Lando program achieved better outcome than the ALA *Freedom from Smoking* method.

Ninety-five percent confidence intervals comparing the ACS *FreshStart* treatment with the average of the two more intensive programs, and the Lando with the ALA *Freedom from Smoking* program on various follow-up measures are presented in Table 3. The *FreshStart* program fared less well than the other two methods on all measures.

Point prevalence abstinence rates at three months were highest in Waterloo (41.6 percent), followed by Des Moines (29.7 percent) and Iowa City (23.7 percent). These differences no longer held at six months and one year. However, at one-year follow-up, sustained abstinence rates were 27.2 percent, 17.0 percent, and 15.0 percent in Waterloo, Des Moines, and Iowa City, respectively ($\chi^2(2) = 6.05$, $p = .048$).

Quit Attempts

There were significant differences in the proportion of subjects in the different treatment groups making quit attempts (Table 4). Subjects in the ACS *FreshStart* program were again less likely to make a quit attempt than those in the other two programs.

Considering only those who made a quit attempt, there was no significant difference in one-year point prevalence

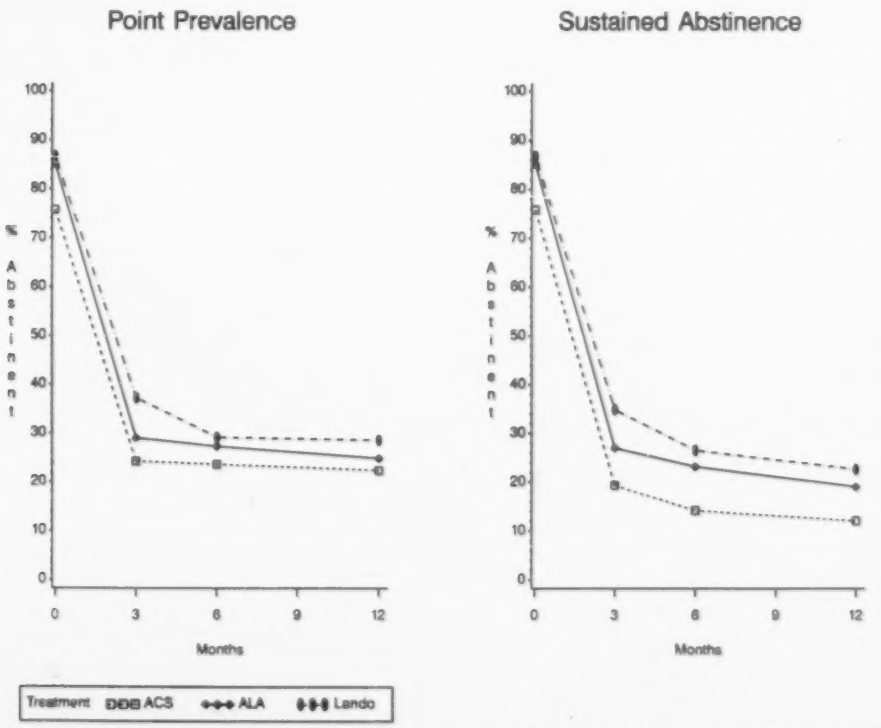

FIGURE 1—Abstinence Outcome at Three Follow-up Times Using Two Abstinence Criteria (Initial abstinence rates (at months = 0) represent initial quitting rates, i.e., those who remained abstinent for 24 hours after quitting.)

Making quit attempt	75.83	85.12	86.74	82.90	.004
1 Yr Point Prevalence	27.09	28.48	31.56	29.15	.59
1 Yr Sustained Abstinence	15.94	22.33	25.58	21.60	.068

*P value is derived from χ^2 statistic with 2 degrees of freedom corrected for DEFF = 1.469.

outcome between the methods but persons in the ACS *FreshStart* program were less likely to sustain abstinence than were those in the other two treatment groups [difference = −8.02%; 95% confidence interval = (−15.37, −0.67)].

Clinic location did not affect the number making quit attempts but did influence one-year sustained abstinence outcome among those attempting cessation (data available on request to author).

Biochemical Validation

Results of biochemical validations performed at one-year tended to be consistent with self-reported abstinence. Of the 80 persons selected for biochemical validation, 73 provided saliva samples. No samples exceeded the cutoff for disconfirmation. Six of the remaining seven persons, while claiming abstinence, refused biochemical validation while one person had returned to smoking between the one-year follow-up and testing. One of those who refused was identified as a smoker by an informant and three additional refusers either did not list or we were unable to contact their informants. If all four of these subjects are counted as smokers (which appears to be an appropriate, albeit conservative, practice) the lie rate would be 5.1 percent (= 4/79). Adjusting the reported outcome data by this factor would not markedly affect absolute abstinence levels and would have little impact upon interpretation of results.

Discussion

The present study represented the first comparative evaluation of the American Cancer Society *FreshStart* and the American Lung Association *Freedom from Smoking* clinic methods. Results indicated relatively modest outcomes for both clinics. The disappointing outcome for the *FreshStart* method on the sustained abstinence measure (12.1 percent sustained abstinence at 12 months) appears noteworthy. This figure would be even lower (10.9 percent) if more rigorous continuous abstinence guidelines had been used (i.e., absolutely no use of tobacco in any form whatsoever).

The reduced number of initial quit attempts with the *FreshStart* method would appear to be largely a function of the absence of a set quit date. However, the present study design does not permit unequivocally eliminating other possible explanations including the lesser total clinic contact. Even so, it should be noted that intensity of clinic contact prior to quit attempts was fairly comparable for the *FreshStart* and *Freedom from Smoking* methods. The major difference in scheduling between the two public service approaches occurred during the maintenance phase rather than in preparation for quitting. Although the results for *FreshStart* are disappointing, it should be remembered that the *FreshStart* method also requires considerably less facilitator contact.

The fact that these programs were offered totally free to participants may have been partially responsible for overall modest abstinence rates. The absence of a fee may also have reduced participants' commitment.

Facilitator bias cannot be dismissed as a possible factor mediating differences between methods. However, every effort had been made to eliminate this bias. Facilitators had no a priori commitment to a given approach. They had been specifically instructed to work within the confines of each method to produce the best possible outcomes. Furthermore, the larger differences occurred between the two public service methods. Differences between *Freedom from Smoking* and the laboratory program (in which the investigators would have been expected to have a vested interest) were less pronounced and were no longer significant at the one-year follow-up.

Differential enrollment in treatment conditions was not a factor in mediating outcome. There were no differences in enrollment in the three clinic programs following the initial informational meeting. It is possible that a limitation inherent in the interpretation of these results may arise from the fact that the unit of randomization and the unit of analysis in this study are different. However, the large sample size provides a measure of confidence in the results.

The location effects were unanticipated. Although no obvious explanation is apparent for the superior outcome in Waterloo, clinics were relatively new to this community. Numerous cessation programs had been offered in both Des Moines and Iowa City. Perhaps smokers in Waterloo responded to the novelty of the clinic programs. Des Moines and Iowa City subjects would have had many previous opportunities to enroll in cessation clinics and these subjects may have been more resistant to quitting. It should be noted that at no point did location effects interact with intervention. The order of outcomes was comparable across all three study communities despite the main effects for location. The fact

that the study results were replicated in three separate communities with a relatively large total subject pool lends increased confidence in their generalizability. Ironically, the Iowa City sample which fared most poorly was younger and apparently less habituated (as indicated by lower daily cigarette consumption) than were the other subject samples.

Although cost-effectiveness analyses were not a formal part of the present study, cost considerations are obviously important.[11–12] Costs of programs can be sharply reduced by use of lay volunteers and donated facilities.[6] Training requirements are minimal. Each of the three methods can be learned in a few hours of formal instruction. Costs that are incurred can be largely defrayed by relatively modest fees to participants (the maximum fee per participant in public service applications of the laboratory-derived clinic method is $75.00). Costs should be lower for the ACS method given the requirement of only four hours of participant contact. These lower costs must be weighed against the reduced effectiveness of this method.

It has proven possible to achieve low-cost technology transfer of the laboratory method. Collaboration between laboratory researchers and a voluntary agency (the American Lung Association of Iowa) has proven critical in effecting this transfer. Especially encouraging is the apparent lack of decay in outcome in the transfer between the laboratory and field settings. There have been virtually no net costs to field sites (often community hospitals). Participant fees have defrayed costs of facilitators and promotion (often promotion has occurred through public service messages).

The American Lung Association of Iowa in the 1988–89 fiscal year reported total expenses of $32,438.70 in overseeing the statewide implementation of 111 laboratory-derived public service clinics reaching approximately 1,000 smokers. Expenses included research and evaluation, travel, facilitator training and updates, printing, postage, computer and software, telephone, personnel, advertising and audiovisuals. These expenses were largely offset by income ($18,235.00), fees charged for facilitator training and updates ($2,982.08), and a grant from an insurance company ($3,187.34). Net expenses were $8,034.28 or approximately $8.03 for each smoker who went through the program. Cost per abstinent smoker at 12 months was $26.77. Considerable public health impact might be achieved through widespread application of this type of collaborative model involving voluntary agency dissemination of validated cessation clinic programs.

The disappointing overall success rates suggest the need for further intervention among non-abstinent subjects. Prevalence outcomes at one year considerably exceeded sustained abstinence figures. Of those subjects who reported abstinence at one year, 41 percent had relapsed during the follow-up period. Schachter[13] has noted that cumulative success rates in self-initiated quitting substantially exceed commonly reported clinical findings for single quit attempts.

Perhaps the spontaneous initiation of renewed quit attempts observed in the present study can be facilitated through systematic intervention. Little research has been devoted to recycling individuals who fail to sustain abstinence. Too much emphasis may have been devoted to one-shot (albeit relatively intensive) treatment approaches. The need for recycling is underscored by the fact that outcomes in our more recent studies have been generally less successful than was true for studies that we undertook five to 10 years ago. This is true despite the fact that smoking history and demographic characteristics of our clinic enrollees have remained remarkably similar over time. More emphasis should be placed on viewing cessation as a process rather than as a discrete event.[14] Given that most quit attempts end in failure, the importance of eliciting multiple attempts over extended periods of time becomes obvious.

APPENDIX

American Lung Association Clinics

The basic American Lung Association clinic format consists of an orientation session and seven additional 90 minute to two-hour sessions over a seven-week period. The first session provided an in-depth discussion of the general health effects of smoking. Emphasis was placed upon the fact that subjects can quit and that help and encouragement to do so would be available in the program. The second session introduced coping strategies for confronting urges to smoke. By the third session, subjects were expected to make a personal commitment to quitting and to state this commitment publicly at the session. Quit Day occurred at this third session. At a fourth session held two days later benefits of quitting were reiterated and possible withdrawal symptoms were discussed.

The remaining sessions were focused upon maintenance and included a consideration of healthier, more enjoyable nonsmoking life-styles. Discussion included relaxation techniques, exercise or physical fitness programs, avoiding weight gain, and coping with tension. Session 7 was a celebration in which subjects elected options such as a wine and cheese party or dinner at a restaurant. This event was intended to emphasize enjoyment of their new life-style (and also to provide practice in confronting what for many might be a difficult situation). At this time awards were given to everyone who completed the program. Although the American Lung Association clinic has approximately one-half the sessions of the Lando clinic, total clinic contact hours for the two methods are approximately equal. Twelve of 31 American Lung Association clinics followed a modified format adopted by the American Lung Association as an alternative for worksite settings. This modified format entailed 10 one-hour sessions. No significant differences in outcome were found between the traditional and modified formats.

American Cancer Society Clinics

Treatment consisted of an orientation session plus four, one-hour group sessions over a two-week period. Emphasis was placed upon individualization of program content by the facilitator and eliciting the active involvement of group members. The focus of treatment was again upon coping strategies and a positive smoke-free life-style. However, instructions to clinic leaders placed relatively more weight upon individual situations as opposed to group process. Subjects were informed that smokers who take two weeks to quit smoking are as likely to be successful as are smokers who take two months to quit. Quitting is again described as a two-part process: 1) stopping, and 2) staying stopped. Unlike the other clinic methods there is no set target date for abstinence, although participants are expected to quit during the latter half of the program.

Laboratory Clinics

Treatment consisted of 16 sessions (approximately 45 minutes to one hour in length) over a nine-week period. The first three weeks were devoted to preparation for quitting and the final six weeks to maintenance. A specific preparation technique involved a nicotine fading procedure adapted from that originally described by Foxx and Brown.[15] Subjects switched brands on a 30–60–90 percent weekly reduction schedule. They were free to choose any cigarette that provided the required nicotine dosage. Subjects also underwent a smokeholding technique similar to that described in 1979 by Kopel, Suckerman, and Baksht* during two clinic sessions held the week prior to the quit date. Smokeholding consisted of two sets of 10 trials separated by a five-minute break.

Subjects attended eight maintenance sessions over a six-week period following the quit date. Considerable emphasis was placed upon relatively unstructured group discussion. In addition, subjects signed contracts calling for specific rewards for abstinence. Group discussion tended to emphasize problem-solving. Subjects were encouraged both to discuss their own problems and to suggest possible strategies for other group members. The laboratory clinics are described in greater detail elsewhere.[6,16]

National Nursing Shortage Commission Announced

A 15-member Commission on the National Nursing Shortage has been established, as announced in the February 23 *Federal Register*. The Commission will advise federal officials—including the DHHS Secretary, the Assistant Secretary for Health, and the HRSA Administrator—on projects implementing the recommendations of the Secretary's Commission on Nursing. The projects should attempt to make optimal use of available resources from federal, state, and local government and private organizations. The recommended projects will focus on five areas:

- Recruitment and the educational pathway;
- Retention and career development;
- Restructuring nursing services and effective utilization of nursing personnel;
- Data collection and analysis requirements; and
- Information systems and related technology in nursing.

The Commission will consist of four ex-officio members and 11 members appointed by the Secretary. The ex-officio members will be:

- A Health Care Financing Administration representative;
- The Chief Nurse Officer of the Public Health Service;
- The Director of the Division of Nursing, HRSA; and
- The Director of the National Center for Nursing Research, National Institutes of Health.

The appointed members will be selected as follows:

- Four from the nursing community;
- Four from health care providers and other nurse employers;
- One from third party payers;
- One representing economics and data policy fields; and
- One from the general public.

Caroline Bagley Burnett, MSN, ScD, a registered nurse and health researcher, was selected Executive Director of the new Commission on the National Nursing Shortage. Formerly she was a research consultant and clinical researcher at the National Cancer Institute and, earlier, assistant professor and oncology program director at the Catholic University of America's School of Nursing.

Benzene, Benzo(a)Pyrene, and Lead in Smoke from Tobacco Products other than Cigarettes

Bruce R. Appel, PhD, Guirguis Guirguis, PhD, In-Suk Kim, PhD, Orlando Garbin, BS, Mario Fracchia, BA, C. Peter Flessel, PhD, Kenneth W. Kizer, MD, MPH, Steven A. Book, PhD, and Thomas E. Warriner, JD

Abstract: Benzene, benzo(a)pyrene (BaP), and lead in mainstream smoke from cigars, roll-your-own (RYO) cigarette and pipe tobaccos were sampled to evaluate their potential health significance. Results with reference cigarettes were consistent with published values, providing support for the methodology employed. The emissions of benzene and BaP, expressed as mass emitted per gram of tobacco consumed, were similar for all products evaluated; for benzene, the mean values for cigars, RYO cigarette and pipe tobaccos were 156 ± 52, 68 ± 11, and 242 ± 126 μg/g, respectively. Mean values for BaP were 42 ± 7 and 48 ± 4 ng/g for cigars and RYO cigarette tobacco, respectively. Lead values were below the limit of reliable quantitation in all cases. The mean benzene concentrations in a puff ranged from 1 to 2 × 10^5 μg/m^3 for cigars, RYO cigarette and pipe tobaccos. For BaP, the puff concentration averaged about 60 μg/m^3 for cigars and RYO cigarette tobacco. The results suggest that smoking cigars, pipes or RYO cigarettes leads to potential exposures which exceed the No Significant Risk levels of benzene and BaP set pursuant to California's Proposition 65. These tobacco products are now required to bear a health hazard warning when sold in California. We recommend that this be adopted as national policy. (*Am J Public Health* 1990; 80:560–564.)

Introduction

Cigarettes sold in the US are required by federal law to bear warnings of their health hazard. Other tobacco products, viz., cigars, pipe, and roll-your-own (RYO) cigarette tobaccos are not covered by federal law. A previous publication discussed California's Safe Drinking Water and Toxic Enforcement Act of 1986 (Proposition 65), including the requirement for warnings on commercial products containing or forming chemicals "known to the State" to cause cancer or other reproductive toxic effects.[1] Accordingly, the levels of three tobacco smoke constituents subject to Proposition 65 regulation, benzo(a)pyrene, (BaP), benzene, and lead, were determined. For benzo(a)pyrene, there is limited evidence of carcinogenicity in humans, but sufficient evidence of carcinogenicity in experimental animals.[2] Benzene has been shown to increase the incidence of leukemia in exposed workers, and to produce cancer in animals at various sites by several routes of exposure.[3] The reproductive toxicity of lead has been well documented in both human and animal investigations.[4]

Tobacco smoke includes both particle-phase and gaseous combustion products.[5,6] The particle-phase material represent about 8 percent (by weight) of the total. The gas-phase constituents include air (58 percent by weight), excess N_2 (15 percent by weight) and vapor constituents (19 percent by weight), the latter being hydrocarbons, oxygenated organic compounds and other gases (e.g., carbon monoxide). Polyaromatic hydrocarbons (PAHs) are found in both phases, the low molecular weight materials (e.g., naphthalene) being in gas phase, together with single ring aromatic hydrocarbons (e.g., benzene), and the five-ring PAH, benzo(a)pyrene (BaP) being almost exclusively in particle phase under usual conditions. Lead in cigarette tobacco smoke exists primarily in the particle phase. Commercial cigarettes from five countries showed a range for lead in mainstream tobacco smoke of 0.4 to 1.0 μg/cigarette in the particle phase, compared with 0.1 to 0.2 μg/cigarette in the gas phase.[7]

Mainstream cigarette tobacco smoke samples are routinely generated with laboratory "smoking machines" using Federal Trade Commission (FTC) standard smoking conditions: a two-second puff of 35 ± 2 ml volume, once/min, and a butt length of 23 mm.[8] FTC guidelines are lacking for RYO cigarette and pipe tobaccos, as well as for cigars. The Tobacco Research Council of London (TRC) specified for cigars the same parameters as used with cigarettes, with a butt length of 25 mm.[9] A cigar smoking protocol using a 1.5 sec puff, 20 ml puff volume, 40 sec puff interval and 33 mm butt length has also been recommended.[10] No standard protocol is available for testing pipe tobacco or RYO cigarettes, to our knowledge.

The present study measured and compared cigars, pipe tobacco and RYO cigarettes, for the levels of benzene, BaP, and lead in their mainstream smoke; and compared the mainstream smoke results to the daily exposure levels of benzene, BaP and lead judged in California Proposition 65 to pose no significant risk. Because of time limitations, pipe tobacco smoke was assessed for benzene levels only.

Methods

Tobacco Products

The tobacco products evaluated are described in the Appendix. One cigar was smoked for each lead or BaP plus benzene sample. The RYO cigarettes were prepared with a rolling machine intended for private use, with a rice paper wrapper ("Abadie" brand), length 70 mm, to which was added a pre-weighed amount of tobacco. Three such cigarettes were smoked per sample. Pipe tobacco was evaluated when smoked in a pipe, as well as in RYO cigarettes, prepared as described above, weighing 1.50 ± 0.02 g, smoking one cigarette per sample.

For pipe smoking, 1 to 2 g of tobacco were smoked in a pre-conditioned wooden pipe (bowl dimensions 20 mm I.D., depth at center 39 mm, stem length 60 mm from center of bowl) requiring 3 to 4 g of tobacco for filling as follows: the pipe was filled loosely with tobacco to the top of the bowl, the tobacco compressed in half, the bowl refilled and the tobacco

© 1990 American Journal of Public Health 0090-0036/90$1.50

compressed to about three-fourths of a full bowl. The tobacco consumed was approximated from the weight difference for the pipe plus tobacco before and after smoking.

Sample Collection and Smoking Parameters

The smoking parameters adopted here for cigars, pipe and RYO cigarette tobaccos retained the puff duration and volume of the FTC guidelines and varied the puff frequency as necessary to keep the tobacco burning and (for cigars) to provide a smoking time <1 hour. Pipe tobaccos were evaluated as RYO cigarettes as well as when smoked in a pipe, to assess whether smoking conditions played a major role in determining emissions of the pollutants measured.

A smoking system (Figure 1) drew air through the cigar, cigarette or pipe for brief periods to simulate a smoker's puff. The system was adjusted to a 35 ± 2 ml puff volume per 2.00 ± 0.05 sec puff using a bubble flowmeter attached upstream of the system. The RYO cigarettes prepared from cigarette tobacco followed FTC smoking parameters (i.e., two sec puff, 35 ml puff volume, once/min, butt length 23 mm). The RYO cigarettes prepared from pipe tobacco employed the same parameters except for puff frequency, which was increased to two/min. Cigar testing followed TRC-recommended parameters (two sec duration, puff volume 35 ml, butt length 25 mm),[9] with puff frequency altered to two/min. With pipe tobacco smoked in a pipe, a puff frequency of 12/min was used. Before smoking, tobacco products were equilibrated at room temperature for 24 to 48 hours in a chamber at about 60 percent relative humidity.

The sampling scheme employed a Gelman A/E glass fiber filter to collect BaP, or an 0.8 μm pore size (Millipore AA) cellulose ester membrane filter to collect particle-phase lead. An 8 × 110 mm glass tube filled with granular, activated charcoal (400 and 200 mg charcoal in the front and rear sections, respectively), downstream of the glass fiber filter, collected benzene with a measured front section collection efficiency >99.99%. The 47-mm diameter filters were contained in a Teflon filter holder. To minimize filter plugging with smoke constituents from cigars, filters were replaced when half the cigar had been consumed. By this strategy, the decrease in flow rate during filter loading was ≤20 percent. The two filters were extracted together to recover the BaP or lead. Single filter collection with ≤20 percent decrease in flow rate was achieved with the other tobacco products. The decrease in flow rate caused an estimated ≤10 percent positive error in calculating the total air volume sampled, and a corresponding negative error in calculated concentrations of benzene and BaP in a puff.

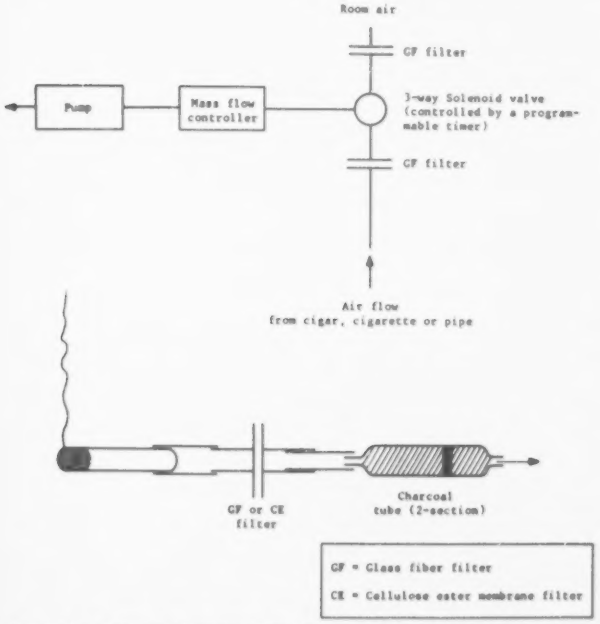

FIGURE 1—Schematic Drawing of the Collection of Tobacco Smoke Particulate and Vapor Phase Constituents

Chemical Analysis

BaP was extracted by one-hour ultrasonic agitation of the filter(s) in 70:20:10 v/v/v dichloromethane-methanol-benzene. Following removal of acidic and alkaline constituents by liquid-liquid extraction, and treatment with silica gel, samples were analyzed for BaP by reverse phase, high performance liquid chromatography, with fluorescence detection. Using NBS Standard Reference Material 1649 (urban dust), the recovery of BaP from the sample cleanup and analysis averaged 77 ± 4 percent. Benzene was extracted from the charcoal-filled collection tubes with CS_2 and directly analyzed by gas chromatography with photoionization detection.[11] Independent confirmation of the identity of the GC peak as benzene, as well as an interlaboratory comparison of benzene quantitation, was provided by gas chromatography-mass spectrometry (GC-MS) analysis on three CS_2 sample extracts. Benzene results from the two laboratories for the three extracts agreed, on average, within 10 percent. Lead was extracted from filter samples in concentrated HNO_3, and analyzed by flameless atomic absorption spectroscopy, using a heated graphite analyzer.[12] Blank trials with unlit tobacco showed no significant levels of BaP, benzene or lead.

Results are reported per gram of tobacco consumed (i.e., the total weight of tobacco consumed during as well as between puffs) as well as per cigar, or cigarette. Tobacco products were also compared based on average concentrations in the air stream sampled (i.e., puff concentrations). Comparison of results among the tobacco products is complicated by differences in puff frequencies. For example, at two puffs/min, a greater proportion of the tobacco will be consumed in generating mainstream smoke, compared to one puff/min. It is inappropriate to normalize results to a common puff frequency (e.g., by dividing results obtained at two puffs/min by two), since increased puff frequencies cause higher burning temperatures, enhance pyrolysis and decrease the amount of combustion or pyrolysis products retained on unburned tobacco in the butt.

Results

Quality Assurance

A Kentucky reference cigarette, type 2R1 (University of Kentucky), was evaluated for benzene and BaP production in the mainstream smoke. The procedures followed were the same as those for RYO cigarettes with cigarette tobacco; three cigarettes (average cigarette weight 1.18 g) were used to load a single charcoal tube. The benzene results for two such charcoal tube samples were 56 ± 2 and 67 ± 6 μg/cigarette (67 ± 2 and 81 ± 6 μg/g of tobacco burned), respectively. These results compare to 75 μg/cigarette reported for a similar Kentucky reference cigarette 1R1,[13] using a commercial smoking machine with the same smoking parameters. Smoke

constituent deliveries for the two reference cigarettes are expected to be equal within about 30 percent.* Our benzene results for reference cigarette 2R1 averaged 18 percent lower than the published results for reference cigarette 1R1. Mainstream smoke BaP results for two trials, corrected for 77 percent recovery, were both 32 ng/cigarette (39 ng/g of tobacco burned). This compares to the 28.4 ± 3.4 ng/cigarette previously reported for this cigarette, using the same (FTC) smoking parameters.[14]

To assess the accuracy and precision of the analysis for lead at the relatively low levels expected, four blank cellulose ester membrane filters were each spiked with 0.1 μg lead from an aqueous solution of lead nitrate, and then subjected to extraction and analysis. The recovery averaged 83 ± 19 percent (n = 4).

Benzene

Mean tobacco smoke results, by brand, are shown for cigars and RYO cigarette tobacco in Table 1. Expressed by amount per cigar or cigarette, the benzene values for cigars and cigarettes showed a wide range of values. Brand F cigars were the only filter-tipped tobacco product evaluated in the present study. Benzene results for these filter-tipped cigars were similar to those for the others. The range in benzene results is reduced when expressed per gram of tobacco burned.

Benzene levels from RYO cigarettes were similar to those for the Kentucky reference cigarettes, smoked following the same parameters, and, expressed per gram of tobacco burned, averaged about a factor of two below those for cigars. This difference reflects, at least in part, the factor of two difference in puff frequency. Table 1 also shows average concentrations calculated for benzene in a puff, as well as the average number of puffs required with each product. The concentrations ranged from 0.7×10^5 to 3.3×10^5 μg/m^3, about 10^4 times those in urban ambient air.[15]

Table 2 summarizes pipe tobacco smoke benzene results for single cigarettes rolled from pipe tobacco, and for the same tobacco smoked in a pipe, expressed per gram of tobacco burned as well as by average puff concentrations. Again, ranges are wide. On average, results for pipe smoking were 2.5 times those in the RYO cigarette configuration. The difference probably reflects the much higher puff frequency used in pipe smoking, 12 vs two puffs/min, and the correspondingly greater proportion of the tobacco consumed in generating mainstream smoke. The mean result in the RYO cigarette configuration, 139 ± 45 μg/g, compares to 156 ± 52 μg/g for cigars, also smoked with two puffs/min. Thus, when tested using the same smoking parameters, pipe tobacco and cigars were not significantly different regarding mainstream smoke benzene levels. The puff concentrations from pipe tobacco smoked in both configurations are similar to those found for cigars and RYO cigarettes from cigarette tobacco.

BaP

The coefficient of variation (C.V.) for BaP measurement, with each brand of cigar or RYO cigarette tobacco evaluated in two or more trials, varied from 3 to 24 percent (Table 1). The BaP levels ranged from 96 to 292 ng per cigar, and were about 40 ng/cigarette for both RYO cigarette tobaccos tested. BaP data for Brand F filter-tipped cigars were not obtained. Expressed per g of tobacco burned, the range in BaP results is sharply compressed, and the results are similar for cigars and cigarettes. Both cigar and RYO cigarette BaP results are also similar to those obtained with the Kentucky reference cigarettes, 39 ng/g. Calculated puff concentrations of BaP showed a correspondingly small range for all tobacco products evaluated, and no difference between cigars and RYO cigarette tobacco, with an overall mean of 61 ± 14 μg/m^3 (C.V. 23 percent). It is unclear why differences in puff frequency between cigars and RYO cigarettes appear to influence benzene levels and not those for BaP. Benzo(a)pyrene concentrations are about 10^5 higher than those usually found in urban ambient air.[16]

Lead

Mainstream tobacco smoke particulate lead results for all cigars and RYO cigarette tobaccos tested were below the limit of reliable quantitation, 0.2 μg/cigar or cigarette.

Discussion

The yields of benzene and BaP, per gram of tobacco burned, in the non-cigarette tobacco products tested here are similar to those previously reported for a reference cigarette. However, the lead values obtained are lower than those in previous work (e.g., 0.4 to 1.0 μg Pb/cigarette cited in reference 7). This is consistent with a decrease in atmospheric lead observed in recent years, concomitant with the

decreased use of leaded gasoline. For example,[17] over the period 1975 to 1984, the highest calendar quarter mean lead concentration decreased at a downtown Los Angeles site from 4.9 to 0.7 μg/m³. Similar decreases have been observed in North Carolina, an important tobacco-growing State.**

Under regulations implementing California's Proposition 65,[18] carcinogens are deemed to pose no significant risk (NSR) if daily exposures do not exceed those expected to produce a lifetime excess cancer risk of 1 in 100,000. The daily NSR level set for benzene is 20 μg, and for BaP, it is 0.06 μg.

The significance of the levels of these chemicals measured in mainstream tobacco smoke can be judged by comparison to the NSR levels. For example, the amounts of benzene in mainstream smoke from burning one 1.2-g RYO cigarette, a 7-g, 16-cm ("Churchill size") cigar (e.g., cigar brand E), or a bowlful (e.g., 3.5 g) of pipe tobacco were approximately 3, 36 and 60 times the NSR level, respectively. The corresponding amounts of BaP from a RYO cigarette and the Churchill-size cigar were approximately 0.9 and five times the NSR level, respectively. Thus, benzene and BaP in mainstream tobacco smoke from less than one Churchill-size cigar, two RYO cigarettes or a bowl of pipe tobacco exceeded daily NSR levels under California's Proposition 65, using simulated smoking protocols. With smokers, actual exposures to these chemicals will vary by the degree to which the smoke is inhaled. Similarly, the puff concentrations reported are not intended to reflect concentrations potentially inhaled by smokers, since the puff is subject to substantial dilution by air not drawn in through the cigarette.

California's interest in limiting toxic exposures, as expressed through Proposition 65, may portend an increased national focus on the adverse health consequences of smoking. Recently, manufacturers of cigars, RYO cigarette and pipe tobaccos have added warning labels for these products sold in California. We recommend that warning labels be made a standard requirement for all such products sold in the US.

Rockefeller Foundation Grants: Global Environmental Program Announced

The Rockefeller Foundation has announced its new Global Environmental Program, a grant-making initiative to "promote the skills, attitudes, relationships and institutions necessary for environmentally sound international development." Whether humans can live in balance with the natural environment and whether all the countries and cultures of the world can achieve a reasonable and just standard of living are two emerging aspects of the same issue which will be addressed by the new program.

The new Global Environmental Program is part of the Foundation's International Program to Support Science-Based Development built on the premise that the well-being of people in developing nations can be advanced in important ways through the application of science and technology. The environmental initiative takes into account, however, that the application of science and technology to development in the industrialized nations has not always been kind to the environment. The challenge before the world community is to promote a more equitable sharing of the world's resources and yet avoid repetition of environmentally unsound development practices.

The Global Environmental Program will begin with four broad areas of interest for grant and fellowship activity:

- supporting young environmental scientists, analysts, policymakers, and community leaders who can be architects of future policy in development and the environment;
- advancing the development of economic analysis which can guide and illuminate the process of environmentally sound development;
- laying the groundwork for multilateral bargains and accords that will be necessary to address selected environmental issues; and
- Seeking innovative ways to help the United States public prepare for new environmental realities.

No special form is required for grant applications. However, they should include:

- a description of the project, with clearly stated plans and objectives;
- a comprehensive plan for the total funding of the project during and, where applicable, after the proposed grant period; and
- a listing of the applicant's qualifications and accomplishments and, if applicable, a description of the institutional setting.

Address grant applications and requests for further information to:

Long-Term Effectiveness of Mass Media Led Antismoking Campaigns in Australia

JOHN P. PIERCE, PHD, PETRA MACASKILL, MAPPSTAT, AND DAVID HILL, PHD

Abstract: A community antismoking campaign began in Sydney, Australia in 1983, and in Melbourne in 1984. These campaigns purchased prime-time television advertising spots to set the community agenda. An intense effort was made to ensure that antismoking activities were maximized at the school, organizational, and community level. Smoking prevalences in both cities from 1981 were fitted with a statistical model to identify any underlying trend, to assess any immediate impact, and to assess the longer term effect of continuing to conduct such campaigns, i.e. to identify any change in the underlying trend. During the years before the antismoking campaigns, there was no observable trend in smoking prevalence in either city. At the beginning of the campaigns, there was an immediate drop of more than two percentage points in male and female smoking prevalence in both cities. Thereafter, a decline of about 1.5 percentage points per year was observed among males. No post campaign trend was observed in smoking prevalence for women in either city. These data support conducting coordinated community campaigns to reduce current smoking prevalence. (*Am J Public Health* 1990; 80:565–569.)

Introduction

Smoking prevalence in Australia did not decline much from 1974 to 1983 according to age standardized comparisons,[1,2] in contrast to the pattern seen in other Western developed countries.[3] For this reason, a number of individual states in Australia introduced a coordinated campaign approach to promoting change in health behavior, as pioneered in cardiovascular disease by the Stanford Three Community Project[4] and the North Karelia Project.[5]

In 1983 in Sydney and in 1984 in Melbourne, the State Health Departments established anti-smoking steering committees composed of personnel from the health departments, the major voluntary organizations, health professional societies, and university public health departments. Television commercials were developed to motivate smokers to quit smoking and to set the agenda for professionals whom the campaign team hoped to involve in promoting nonsmoking, given the evidence of the effectiveness of medical advice.[6–8] The effectiveness of school education programs[9] also made establishing such programs a high priority within the community. Although the campaign committees in both cities shared campaign materials and ideas, the actual activities undertaken within each city were dictated by the perceived local needs and opportunities.

A detailed evaluation was undertaken of the first year of the campaign in Sydney using Melbourne, which did not have a campaign that year, as a reference community.[10,11] More than 80 percent of the population of Sydney remembered the television commercials. After these commercials were aired, use of services such as a telephone quit line and enrollment in cessation classes increased. The campaign was also associated with higher levels of intention to quit in Sydney, a variable that had previously been shown to be associated with actual quitting.[12] Changes in smoking prevalence during the first campaign year were assessed by self-reported smoking behavior (after validation with salivary cotinine[13]) from both cross-sectional and longitudinal surveys. No decrease was seen in the reference city, Melbourne. The pooled estimate of the difference in smoking prevalence attributable to the campaign was 2.8 percent (95% confidence interval = 0.5, 5.1).[11]

Since 1984, the campaigns have continued in both Melbourne and Sydney, spearheaded each year by commercials shown on prime time television for six to eight weeks during the winter months. In this paper, we assess the long-term effect of this approach to reducing the prevalence of smoking. We used data from both cities to determine whether these key intermediate goals were achieved:

- High public awareness of the campaign during each campaign year;
- A strengthening of the stand of health professionals, particularly physicians, against smoking;
- An increased proportion of the smoking population who both believed that smoking was harming their own health and also were being influenced by their social network to quit smoking.

The effectiveness of the campaign was assessed by using self-reported smoking data from 1981 to 1987 for each city.

Methods

General Design

This project has a before and after design in each of two intervention cities with a temporal lag of 12 months between the onset of the intervention in the second city. Prevalence data were obtained for several years before the onset of the intervention, as well as for the duration of the campaign. In 1983 and 1986, more detailed questions about health beliefs, intentions, and social influences were asked in each city. Small random surveys were undertaken approximately two months after the completion of each component of the television campaign to assess recall of commercials.

Mass Media Used in Campaigns

Television—In both Sydney and Melbourne, television advertising made up about two-thirds of the media budget for the campaigns. Typically, commercial spots were purchased during prime or fringe time for approximately four weeks out of eight at the start of the campaign year. Approximately 40 spots per week were shown during a schedule designed to ensure at least 50 percent market penetration in the Sydney

From the Department of Public Health, University of Sydney, New South Wales (Pierce, Macaskill) and the Center for Behavioral Research in Cancer, Carlton, Victoria, Australia (Hill). Address reprint requests to John P. Pierce, PhD, Director, Population Studies in Cancer Prevention, UCSD Cancer Center, T-010 225 Dickinson St., San Diego, CA 92103. This paper, submitted to the Journal March 28, 1989, was revised and accepted for publication October 30, 1989.

© 1990 American Journal of Public Health 0090-0036/90$1.50

and Melbourne metropolitan areas during each year of the campaign.

Production of commercials followed research on messages that were likely to be effective among the target audience. These commercials were designed to use strong visual images of the health consequences of smoking. Further, they sought an emotive response among the audience to ensure attention and to maximize the likelihood that viewers would reassess the hazards of smoking and then possibly quit in the near future (for description, see Appendix).[12,15] All of the commercials ended with a "Quit line" telephone number that people could call 24 hours a day to hear a recorded informative and encouraging message about quitting smoking.

Other Mass Media—A concerted effort was made to coordinate all mass media advertising around a central theme that was dictated by the message in the major television commercial being run at the time. For billboard advertising, a simple message from the television commercial was displayed at numerous sites, especially those near mass transit locations. Advertising in newspapers included the normal large advertisement and, in Sydney, a section was purchased for journalistic coverage of smoking-related events and issues. Antismoking skits by major personalities complemented the normal quit smoking commercials on the radio. In addition, the campaign generated many news releases and events that resulted in substantial news coverage in all the mass media.

Physician's Offices

In both cities, there was active collaboration with the Australian Medical Association to develop and distribute printed resources that physicians could use to encourage and help their patients quit smoking. In Melbourne, a special training videotape about smoking was produced and shown widely to family physicians. In Sydney, a special training program was available to family physicians to enable them to more effectively counsel their patients to stop smoking.[16]

Schools

In Sydney, two school programs were developed: a comprehensive kindergarten through 12th grade curriculum and a grade-specific peer or teacher led curriculum. By 1986, 80 percent of all schools in Sydney had at least one person who was trained by the campaign team in conducting the program of choice for that school. Sixty-four percent (88 percent of the 73 percent who responded) of these schools reported using these materials during the 1986 academic year. Further, the campaign team sponsored theatre performances, rock concerts, and sports activities with antismoking themes.

In Melbourne, kindergarten through 12th grade curriculum resources on smoking were made available to all schools, and project workers encouraged and helped teachers to use these resources. By 1986, in sample surveys of school children in both Sydney and Melbourne, more than 70 percent of 12–15-year-olds reported receiving at least minimal health education about smoking during the year.[17]

Other Community Activities

Each year, the campaigns either organized smoking cessation clinics or informed the population in each city about the availability of clinics. Training programs were available for health educators who might be appointed to local government or other affiliated positions. In addition, quit smoking display stands were regularly erected and staffed in shopping malls and at public fairs.

Assessing Smoking Prevalence

Between 1981 and 1987, 68,136 males and 70,634 females aged 16 years and over from the suburbs of metropolitan Sydney and Melbourne were interviewed in their homes as part of an ongoing weekly survey. Sampling procedures, reported in detail elsewhere,[11] involved selecting a household starting point at random from the electoral roll (in Australia, it is compulsory for citizens over 17 years of age to be registered on the electoral roll). Field interviewers proceeded to move from house to house in a clockwise direction until they obtained a cluster of 10 interviews from separate households. Within the household, the youngest person aged 16 years and over of a selected sex was interviewed. The resulting sample has been shown to be representative of the population on major sociodemographic variables.[11]

A smoker was defined as anyone who responded positively to questions on whether he or she smoked factory-made cigarettes, roll-your-own cigarettes, cigars, or a pipe. In two separate subsamples, self-reported smoking was validated with biochemical analysis of saliva for the presence of cotinine.[13]

Measuring Campaign Exposure

For each year of the campaign, recall of the television commercials was assessed on separate random samples of the population of at least 1,000 persons in the three months following the completion of the television phase of the campaign. Shortly after the completion of each annual television campaign, a subsample of persons in Sydney were shown a set of six still photographs taken from the commercials. They were first asked whether they had seen the commercial and, if they responded yes, what the message was (care was taken that no "giveaway" words or cigarettes appeared in the photographs). In Melbourne, the respondents were asked whether they had seen any television commercials against smoking, recently. The interviewer then probed all positive responses and recorded details of the message recalled.

Assessing Predictors of Quitting

In 1983 and 1986, additional random samples of the population of Sydney and Melbourne were surveyed. The Sydney survey included 271 smokers in 1983 and 557 smokers in 1986. The Melbourne sample included 217 smokers in 1983 and 550 smokers in 1986. Smoking respondents were asked to agree or disagree with a set of statements previously shown to be scales representing health beliefs and social influences.[12] The items in the health belief scale were "Smoking cigarettes doesn't greatly affect my health," "The problems with smoking only affect heavy smokers," and "I'd rather enjoy life as a smoker than live a little longer without cigarettes."

The items in the social influence scale were "I find that my smoking annoys people around me who don't smoke," "What I dislike about smoking is the smell that it leaves on clothes", "All the physicians that I know are strongly against smoking," "My close friends would prefer that I didn't smoke," and "I find that people are talking a lot more about smoking and the problems of giving up." Internal consistency reliability (Cronbach's alpha) on these scales have been

previously reported at 0.57 on the health benefit scale and 0.56 on the social influence scale.[12]

Statistical Analysis of Prevalence

For the purpose of analysis, data were grouped into intervals of six months for each city and were adjusted for age and sex to the estimated population of Sydney in 1986 using direct standardization. Salonen, *et al*,[18] have suggested using multiple linear regression models to evaluate the effectiveness of community-based intervention programs by testing for interaction effects between the type of community (intervention or reference) and the timing of the onset of the intervention effect. In this study, which lacked a nonintervention community, the following simplified form of the suggested model was fitted to each of the data sets.

$$P = \beta_0 + \beta_1 C + \beta_2 T + \beta_3 CT + \beta_4 S + \text{error}$$

where P represents the prevalence of smoking,

C is a binary indicator variable representing whether the data are from the precampaign (C = 0) or the postcampaign (C = 1) period,
T is the trend variable for time,
S is a binary indicator of season with a value of 1 for the first six months and −1 for the second six months of each year.

Using this model, β_0 is an estimate of the expected prevalence at the start of the campaign (T = 0) given the underlying trend in the precampaign period. β_1 is an estimate of the immediate effect of the intervention (as such an effect was demonstrated in a previous paper[15]). β_2 estimates the underlying trend in prevalence over the whole time period, and β_3 estimates the change in this underlying trend associated with the commencement of the campaigns. The coefficient β_4 provides an estimate of the effect of seasonal variation on the data. For each analysis, a model which included all the explanatory variables described above (full model) was fitted. A parsimonious model (adjusted for seasonal effect) was then developed by using backward elimination to remove variables, other than S, with the chosen level of significance set at 0.05. This reduced model identifies the pattern of change in prevalence in relation to the timing of the campaigns. A series of curvilinear (polynomial) models were also fitted to the data. Quadratic and cubic models were compared with the linear parsimonious models described above to assess whether the more complex models fit the data better.

Results

Population Knowledge of the Campaign

We assessed awareness about the antismoking campaign by asking people in each city what they recalled about the most public aspect of the campaign, the television commercials (Table 1). For all the major commercials in these campaigns, there was little difference between the recall of the commercial and identification of an appropriate antismoking message. In both cities, more than two-thirds of the community knew that an antismoking campaign existed in the years that such campaigns were conducted.

Action by Physicians

During the campaign, physicians' roles were assessed by asking respondents how strongly the physicians were against smoking; these data were then divided by age and sex for each city in 1983 and 1986 (Figure 1). Before the campaign, only 15 percent of males and females smokers over age 40 in Sydney thought their physicians were strongly against smoking. By 1986, this had increased dramatically to 47 percent for males and 50 percent for females. In those under the age of 40 in Sydney, this proportion increased from 36 percent to 48 percent in males and from 28 percent to 46 percent in females. In Melbourne males, this proportion increased from 35 percent to 41 percent in those under 40 years and from 28 percent to 35 percent in those over 40. In Melbourne females, this proportion increased from 27 percent to 47 percent in those under 40 years and from 33 percent to 37 percent in those over 40 years.

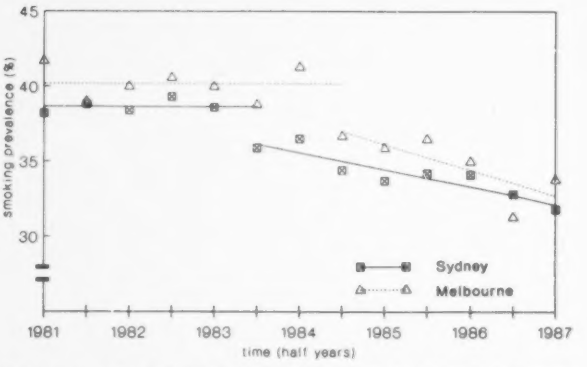

FIGURE 1—Age-Standardized Smoking Prevalence for Males in Sydney and Melbourne, 1981 to 1987

The Health Belief/Social Influence Variable

A previous study[12] had demonstrated that only a combination of personal beliefs about smoking and the environmental influences to quit was associated with an increased likelihood to quit. This proportion reporting both social influence and health beliefs was low in those over the age of 40 years in Sydney in 1983 (males, 10 percent; females, 12 percent). By 1986, this proportion had increased to 29 percent in males and 27 percent in females. In those under 40 in Sydney, males increased from 34 percent to 53 percent and females increased from 30 percent to 44 percent. In those over 40 years in Melbourne, males increased from 21 percent to 29 percent and females increased from 22 percent to 32 percent. In those under 40 years in Melbourne, males increased from 30 percent to 43 percent and females increased from 31 percent to 48 percent.

Smoking Prevalence

We considered both the full and parsimonious statistical models fitted to the age-standardized data for men and

TABLE 1—Percentage of Males and Females Who Recalled Television Advertising in Sydney and Melbourne

Melbourne (unaided)			
1984	70	67	886
1985	73	68	1,818
1986	68	67	1,830

*Only 14-to-19 year-olds.

women separately for each city. For men, these models fit the data very well, explaining 96 percent of the variation in Sydney and 91 percent in Melbourne. For females, the best models did not fit quite so well, explaining 72 percent of the variation in the Sydney sample and 79 percent in the Melbourne sample. However, the most parsimonious model for the Melbourne women sample was not consistent with the other models. A consistent model fitted almost as well and explained 68 percent of the variation.

Figures 1 and 2 are graphical representations of the trends identified in the parsimonious models in conjunction with the observed data. For this presentation, the consistent model was chosen for Melbourne women.

Thus, the best estimate of smoking prevalence among Sydney men (Table 2) indicated that prevalence did not change in the three years before the campaign (June 1983) and was 38.7 percent ($\hat{\beta}_0$ in the parsimonious model). From 1981 to 1987, there was no significant underlying trend in smoking prevalence other than that associated with the campaign. The introduction of the campaign coincided with an estimated immediate drop in smoking prevalence of 2.5 percentage points in that six-month period. Continuation of the campaign was associated with a further drop of 1.12 percentage points per year ($2 \cdot \hat{\beta}_3$). These estimates are consistent with those provided by the full model.

For women, smoking prevalence had again been constant during the years before the campaign and was 31.6 percent in Sydney and 29.8 percent in Melbourne. In Sydney, there was an immediate drop of 2.6 percentage points associated with the introduction of the campaign but smoking prevalence did not significantly decline in the later years of the campaign. Again, this estimate is consistent with that from the saturated model.

Men in Melbourne responded similarly to those in Sydney. As Table 3 shows, the expected prevalence of smoking at the beginning of the campaign (June 1984) was 40.1 percent ($\hat{\beta}_0$). Again, there was no underlying trend. With the start of the campaign, there was an immediate drop of 2.9 percentage points. A further decline of 1.9 percentage points per year occurred in conjunction with the continued campaign. Once again these estimates are consistent with those from the full model.

In Melbourne, two models fitted the data and, as indicated earlier, model 2 is the preferred model. Smoking prevalence prior to the campaign was 30.9 percent. The immediate effect of the campaign was a 2.5 percentage point drop in smoking prevalence, again with no subsequent decline associated with the continued campaign. However, in this instance, the estimate from the full model is very different, highlighting the uncertainty that exists as to the true underlying model.

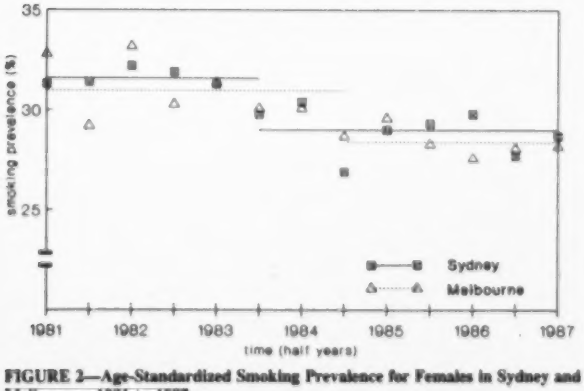

FIGURE 2—Age-Standardized Smoking Prevalence for Females in Sydney and Melbourne, 1981 to 1987

TABLE 2—Statistical Models for Smoking Among Males and Females in Sydney

		Full Model Estimate (SE)	Parsimonious Model Estimate (SE)
Sydney Males	$\hat{\beta}_0$	39.06 (0.67)	38.67 (0.28)
	$\hat{\beta}_1$	−2.91 (0.79)	−2.52 (0.49)
	$\hat{\beta}_2$	0.13 (0.20)	
	$\hat{\beta}_3$	−0.69 (0.22)	−0.56 (0.10)
	$\hat{\beta}_4$	−0.04 (0.18)	−0.04 (0.17)
		(R^2 = 0.96, 8df)	(R^2 = 0.96, 9df)
Females	$\hat{\beta}_0$	031.69 (1.02)	31.56 (0.42)
	$\hat{\beta}_1$	−2.11 (1.20)	−2.61 (0.54)
	$\hat{\beta}_2$	0.05 (0.31)	
	$\hat{\beta}_3$	−0.23 (0.34)	
	$\hat{\beta}_4$	0.38 (0.27)	0.32 (0.26)
		(R^2 = 0.77, 8df)	(R^2 = 0.72, 10df)

Comparison with other Models

The goodness of fit of these parsimonious linear models was compared with quadratic and cubic models. In each case, the best-fit linear model was a superior fit to either of the alternative models, except for Melbourne women, again emphasizing the problems in interpreting this set of data.

Discussion

This study suggests that smoking prevalence in the two major Australian capital cities did not decline prior to the campaign, as previously observed for the period 1974 to 1980 for Australia as a whole.[1–3] The mass media led antismoking campaigns coincided with a marked drop in smoking prevalence during the six-month period immediately following the start of the campaign for all persons in Sydney and for men in Melbourne (the effect on Melbourne women is less clear). The estimated size of this immediate effect was 2.6 percentage points in Sydney. A larger 2.9 percent effect of the antismoking campaign was seen among Melbourne men 12 months later. If we accept the model that suggests that women in Sydney and Melbourne reacted similarly to the antismoking campaign, the campaign immediately reduced smoking prevalence in Melbourne by 2.5 percent, an amount

TABLE 3—Statistical Models for Smoking Among Males and Females in Melbourne

		Full Model Estimate (SE)	Parsimonious Model Estimate (SE)

	$\hat{\beta}_1$	−0.53 (1.10)		−2.52 (0.61)
	$\hat{\beta}_2$	−0.29 (0.19)	−0.37 (0.07)	
	$\hat{\beta}_3$	−0.04 (0.30)		
	$\hat{\beta}_4$	0.64 (0.28)	0.65 (0.25)	0.56 (0.30)
		(R^2 = 0.80, 8df)	(R^2 = 0.79, 10df)	(R^2 = 0.68)

similar to the estimates of the effect obtained in both men and women for Sydney one year earlier. In the alternative model, women in Melbourne were the only group who recorded a decreasing prevalence of smoking during the precampaign period. Given that there was no downward trend in smoking prevalence throughout the 1970s,[1-3] this model must be considered less plausible.

For men in both cities, continued antismoking campaigns were associated with an average continued decrease in smoking prevalence of approximately 1.5 percent per year. The situation for women is less clear, but suggests that the continued campaigns in Sydney and Melbourne were not associated with any further decrease in smoking prevalence among women.

This analysis of changes in community smoking prevalence does not consider the effect that such campaigns may have on uptake of smoking. In any given year, the influence of new smokers between the ages of 16 and 20 years (the teen years included in this data set) on the overall prevalence will be small. Before we can conclude how effective these campaigns really are, changes in the uptake of smoking among teenagers need to be explored. However, even with the effect on uptake of smoking being unresolved, this study supports conducting coordinated mass media antismoking campaigns (using purchased television time) as an effective way to reduce smoking prevalence in the community. Whether conducting campaigns for up to four consecutive years is cost-effective will be the topic of a subsequent paper.

A Twin Study of the Effects of the Vietnam Conflict on Alcohol Drinking Patterns

JACK GOLDBERG, PHD, SETH A. EISEN, MD, MSC, WILLIAM R. TRUE, PHD, MPH, AND WILLIAM G. HENDERSON, PHD

Abstract: This study examines the association between military service in Southeast Asia and alcohol drinking patterns in 2,169 male-male monozygotic twin pairs who both served on active military duty during the Vietnam era (1965–75). Data on alcohol drinking were collected in 1987 by mail and telephone interview. The alcohol drinking measures include three indicators of abstention (lifetime abstainer, lifetime non-regular drinker, and current abstainer) and two indicators of consumption (average daily ethanol consumption and high consumption). In unadjusted and co-twin adjusted analyses, neither service in Southeast Asia nor combat exposure was significantly associated with any measure of abstention. In the co-twin adjusted analysis, there was no association of Southeast Asia service and combat exposure with average daily ethanol consumption. After adjustment for co-twin effects, 4.0 percent of non-Southeast Asia veterans were high consumers compared to 6.7 percent of Southeast Asia veterans who served in high combat. We conclude that prior military service in a war zone has a relatively modest long-term effect on the alcohol drinking patterns of male veterans. (*Am J Public Health* 1990; 80:570–574.)

Introduction

The relationship between service in the military and alcohol drinking patterns is a subject of considerable debate. Numerous clinical studies have concluded that veterans have high rates of alcoholism.[1–3] The evidence for increased alcohol consumption among veterans in non-clinical population samples is equivocal; some studies conclude that increased consumption among veterans is a function of demographic differences between veterans and nonveterans,[4,5] while other more recent research indicates that veterans consume more alcohol than nonveterans regardless of demographic differences.[6]

A number of investigations have examined the association between military service in Southeast Asia and alcohol consumption. Some studies have found that service in Southeast Asia and exposure to combat are associated with increased rates of alcoholism and problem drinking,[7,8] while other research has failed to demonstrate any association with alcohol consumption patterns.[9–12]

The potential for selection bias is a fundamental problem in all studies of alcohol drinking among veterans. Observed associations between military service experience and alcohol drinking patterns may simply reflect an underlying association of predispositional characteristics with both military service experience and alcohol drinking. The present study addresses this problem by examining alcohol drinking in monozygotic twin pairs contained in the Vietnam Era Twin Registry.

Methods

Data Sources and Study Eligibility

The Vietnam Era Twin Registry contains 7,375 male-male twins who both served in the military during the official Vietnam era (May 1965-August 1975). A complete description of the development of the registry can be found elsewhere,[13] and only a brief overview is presented here.

A survey of all twins on the registry was conducted in early 1987, with the goals of collecting information on a wide range of physical and psychological indicators of health. The overall case-wise response rate was 74 percent and the pair-wise response rate was 65 percent or 4,774 pairs. Twins were eligible for the present study if: both members of the pair responded to the survey, the pair was originally ascertained from the US Department of Defense computer files, and complete information was available for all alcohol drinking measures. After applying the exclusion criteria, the final number of eligible twin pairs was 4,048.

Zygosity was evaluated by using a series of questions on twin similarity and limited blood group typing obtained from the military records.[14] Of the 4,048 pairs meeting the eligibility requirements for the present study, 2,169 (53.6 percent) were monozygotic, 1,773 (43.8 percent) were dizygotic and 106 (2.6 percent) were of indeterminant zygosity. The present study focuses exclusively on the monozygotic twin pairs.

Service in Southeast Asia and Combat Exposure

Military service in Southeast Asia was determined by the response to the following question: "When you were in the military, were you stationed in Vietnam, Laos, or Cambodia; in the waters in or around these countries; or fly in missions over these areas?" Those men who responded in the affirmative were then asked a set of questions about 18 specific combat roles or experiences (see Appendix A). For each item the veterans indicated whether they had that role or experience while serving in Southeast Asia. An index of combat exposure was constructed by taking the summation of all positive responses for an individual. For analytical purposes the combat index was grouped into five levels: (non-Southeast Asia service; Southeast Asia service, no combat; low, combat index = 1–2; medium, combat index = 3–6; high, combat index > 6). Elsewhere,[15] we have demonstrated that in a subset of twins who completed the health survey twice more than a year apart, concordance was high (weighted kappa = 0.84) for the combat exposure index. Likewise, the combat index was found to be significantly correlated with objective indicators of threat to life and limb as measured by combat medals and decorations.

Measures of Alcohol Drinking

A negative response to having had more than 20 alcoholic drinks in their entire life defines a lifetime abstainer. Veterans who were not lifetime abstainers, were asked at what age they started drinking alcoholic beverages regularly; as part of the response option to this question the veteran could indicate that he never drank regularly. This is referred to as lifetime non-regular drinker. The next question asked if the veteran drinks alcoholic beverages now. This provides a third measure of alcohol abstention which separates current drinkers from noncurrent drinkers. It should be noted that the lifetime abstainer measure is subsumed by the lifetime non-regular drinker measure, which is subsumed by the current abstainer measure.

For men who are current drinkers quantity was obtained as the average number of drinks consumed on days when the veteran had at least one drink; frequency was obtained in terms of the average number of days per week that the veteran had at least one drink. If the ethanol content of an unspecified drink is assumed to be 0.5 ounces, then average daily ethanol consumption can be calculated as: (frequency × quantity × 0.5)/7. Following the guidelines of the National Institute of Alcohol Abuse and Alcoholism,[16] average daily ethanol consumption can be categorized into four drinking levels: abstainers, average intake of 0.0 ounces ethanol daily; light drinkers, 0.01–0.21 ounces ethanol daily; moderate drinkers, 0.22–0.99 ounces ethanol daily; heavy drinkers, 1.00 or more ounces ethanol daily. A second measure of alcohol consumption is constructed based on the number of ounces of ethanol corresponding to the upper fifth percentile of the average daily ethanol consumption distribution. This measure, referred to as high consumption, conformed to a usual intake of five drinks per day (2.5 ounces of ethanol) in the present study.

Reliability of Alcohol Drinking Measures — In 1985 a pilot study was conducted of 150 veteran twin pairs born in the State of Connecticut. This pilot study was designed as a field test of the methodology to be used in the main study. The measures of alcohol drinking in the field test and the subsequent survey were identical. Because these 150 twin pairs were included in the main study using the Vietnam Era Twin Registry it is possible to evaluate the reliability of the five measures of alcohol drinking.

Complete alcohol drinking data were available from 191 individuals from both studies. Lifetime abstention had a kappa of 0.43, a Yule's Y[17] of 0.77, and a 97 percent overall agreement. Considerably less reliable was the lifetime non-regular drinker measure, which had a kappa of 0.10, Y of 0.37, and a 82 percent overall agreement. The current abstainer measure had a kappa of 0.44, a Y of 0.48, and an overall agreement of 78 percent.

Both of the alcohol consumption measures demonstrated similar levels of reliability. Average daily ethanol consumption had a weighted kappa of 0.55; overall agreement was 81 percent. The measure of high consumption had a kappa of 0.57, a Y of 0.72 and an overall agreement of 92 percent.

Statistical Analysis

The analysis begins by randomly selecting one member of each monozygotic twin pair as the index twin and calculating the association between Southeast Asia service and combat exposure with each of the five alcohol drinking measures. This yields the association of Southeast Asia service and combat exposure with alcohol drinking, unadjusted for co-twin effects. Hypothesis testing for these contingency tables uses standard Chi-square methods and the Mantel extension to test for a linear trend in proportions when appropriate.[18]

The potential confounding effect of co-twin alcohol drinking on the association between index twin alcohol drinking and military service in Southeast Asia is addressed using a logistic regression model. In this model, index twin alcohol drinking is the dependent variable while co-twin alcohol drinking and index twin military service in Southeast Asia are the independent variables. The logistic regression model, adapted for twin data, provides an estimate of the probability of an index twin having an event (e.g., being a lifetime abstainer) based on the co-twin's event history and the index twin's service in Southeast Asia or combat exposure.[19] Hypothesis testing is conducted by dividing the logistic regression coefficient for Southeast Asia service or combat exposure (entered as a five level ordinal variable) by its respective standard error; when squared this follows a Chi-square distribution with one degree of freedom.

The potential confounding effects of demographic and military service factors were examined in a logistic regression model that already included co-twin alcohol drinking. Confounding factors include: years of education at enlistment, branch of service, length of active duty military service, age at enlistment, calendar year of discharge, and score on a general aptitude test taken at enlistment. These factors were examined both singly and in combination, and did not substantially alter the results from the co-twin adjusted analysis.

Results

Table 1 displays the nearly identical distribution of the three measures of alcohol abstention and the two measures of alcohol consumption for index twins and co-twins separately.

Table 2 displays the joint frequency distribution of the alcohol drinking measures with service in Southeast Asia and combat exposure for index twins. There is no evidence of a trend in the prevalence of lifetime abstention, lifetime non-regular drinking, and current abstaining with increasing levels of combat exposure. Conversely, veterans who served in Southeast Asia tend to consume more alcohol than

veterans who did not serve in Southeast Asia (p = 0.053). The prevalence of light and moderate consumption is similar regardless of where a veteran served, but there are 4.4 percent more Southeast Asia veterans than non-Southeast Asia veterans who are heavy alcohol consumers. The extent of combat exposure is directly associated with increased average daily ethanol consumption. Non-Southeast Asia veterans and Southeast Asia veterans who experienced no combat consume about the same amount of alcohol, but veterans who have been exposed to either medium or high combat are found to consume more alcohol. When high consumption is examined, a 2.4 percent excess of high consumers is found in Southeast Asia veterans compared to non-Southeast Asia veterans. Further, a nearly monotonic gradient is observed in the prevalence of high alcohol consumption with combat exposure.

The association of the five alcohol drinking measures with Southeast Asia service and combat exposure, after adjustment for co-twin effects, is displayed in Table 3. None of the three abstention measures as well as average daily ethanol consumption are associated with Southeast Asia service or combat exposure. However, of all index twins who served in Southeast Asia, 5.6 percent are classified as high consumers, compared to 3.9 percent of index twins who did not serve in Southeast Asia (p = 0.048). Similarly, the ordinal index of combat exposure remains positively correlated with the co-twin adjusted prevalence of index twins who are classified as high consumers (p = 0.034).

Discussion

Our results demonstrate a complex pattern of association between military service experience and alcohol drinking patterns. The abstention measures are not associated with military service experience in either the unadjusted or adjusted analysis. In the unadjusted analysis there is a strong relationship of both measures of alcohol consumption with Southeast Asia service and combat exposure. In the cotwin adjusted analysis, average daily ethanol consumption is no longer significantly related to service in Southeast Asia and combat exposure; the association of high consumption with Southeast Asia service and combat is substantially diminished.

What is the likelihood that our findings are due to bias? The principal biases that are likely to be operating in this study relate to uncontrolled confounding, non-response, and flaws in measurement due to the self-reporting of military service experience and alcohol drinking. The principal uncontrolled confounding factor in this study is the pattern of alcohol drinking prior to entering military service. We chose not to collect measures of pre-military service alcohol drinking because of the potential of biased recall. It seems highly probable that the recollection of alcohol drinking patterns 15 to 20 years ago might be influenced by whether a veteran served in Southeast Asia.

Non-response bias might distort our results if veterans who responded are systematically different from veterans who did not respond *and* this difference is related to both alcohol drinking and military service in Southeast Asia. To gain further insight into the possibility of non-response bias we compared the association of Southeast Asia service with demographic and military service confounding factors (years of education at enlistment, branch of service, length of active duty military service, age at enlistment, calendar year of discharge, and score of the general aptitude test taken at enlistment), in responders and nonresponders. This analysis revealed that the potential for bias exists for education at enlistment and age at enlistment. In particular, education at enlistment was directly related to the probability of Southeast Asia service in responders and inversely related to the

probability of Southeast Asia service in non-responders. Likewise, there was no difference in Southeast Asia service by age at enlistment in responders, but in non-responders there was an increased probability of serving in Southeast Asia for veterans who enlisted after the age of 19.

Bias due to self-reported military service experiences is unlikely to provide an explanation for our results. The measurement of Southeast Asia service is in accord with Southeast Asia service as determined from the military record (kappa = 0.86). We have previously demonstrated that the index of combat exposure is reliable and valid.[15] Likewise, the five alcohol drinking measures used in this study demonstrated acceptable reliabilities.

It is difficult to relate our findings to previous research on alcohol drinking among Vietnam era veterans[7,8,11,20,21] because of the major methodological differences among studies. The definition of "exposed" and "unexposed" cohorts is highly variable across studies. Some compare Vietnam era veterans with non-veterans without any measure of actual service in Southeast Asia[22] while others compare combat exposed and non-exposed Southeast Asia veterans without any non-veteran comparison group.[20] Each of the studies uses a different set of indicators for alcohol drinking behavior, ranging from a diagnosis of alcohol abuse and dependence,[8] to measures of usual alcohol beverage consumption.[21] The time interval between exposure and the measurement of alcohol drinking behavior also displays great variability across studies. For example, Robins'[10] initial data collection took place within two years of discharge from active duty while Kulka, *et al*,[12] collected data more than 15 years following discharge. Finally, and perhaps most importantly, there are major differences in the way each study addresses the issue of confounding. If factors related to both military service and alcohol consumption are not adequately controlled in the study design or analysis, then the observed results could be wholly or partially confounded.

Boscarino,[21] using data collected in 1977, found a positive association between service in Southeast Asia and three measures of alcohol consumption (usual daily intake, heavy drinking during the past 30 days, and binge drinking). That study is especially troublesome since it failed to exclude females from the analysis and the confounder adjustment was based solely on demographic factors. In a recent study, the Centers for Disease Control[8] found an increased prevalence of alcohol abuse and dependence in Southeast Asia and combat exposed veterans compared with non-Southeast Asia veterans. That study controlled for potential confounders by restricting the study participants to male Army veterans and by matching Southeast Asia veterans to non-Southeast Asia veterans based on period of service and age. During the analysis numerous potential confounders were examined and found to have no effect. However, the analysis failed to account for familial alcohol drinking patterns.

Card[9] used a single question on heavy alcoholic beverage intake to compare an age-matched cohort of non-veterans, veterans who did not serve in Southeast Asia, and veterans who served in Southeast Asia. Using a complex research design that involved matching on over 50 premilitary service factors, she found no difference in the prevalence of heavy drinking according to service in Southeast Asia. Roth[11] found a small but significant association between military service in Southeast Asia and a composite measure of alcohol intake and problem drinking, after multi-factor adjustment; she found no association between combat exposure and the same composite drinking measure. Yager, *et al*,[7] using a slightly different measure of alcohol drinking in this same cohort, came to a different conclusion; neither an indicator of heavy daily alcohol consumption nor a problem drinking scale was related to service in Southeast Asia. A significant association was found between combat and a measure of heavy daily

consumption. These conflicting reports obtained from the same data decrease the credibility of both studies.

Based on our findings, and the inconsistent evidence from previous research, we conclude that service in Southeast Asia and exposure to combat have relatively modest long-term effects on the alcohol drinking patterns of Vietnam era veterans.

APPENDIX A

Eighteen Indicators of Combat Exposure

1. In an artillery unit which fired on the enemy
2. Flew in an aircraft (reconnaissance, or fixed wing F-14, B-52, etc.)
3. Flew helicopter attack gunships or medivacs
4. Stationed at a forward observation post
5. Tunnel rat checking enemy base camps
6. Served on river patrol or gunboat
7. Demolitions expert in the field
8. Assigned to graves and registration to retrieve dead bodies from the field
9. Served as a medic in combat
10. Received incoming fire
11. Encountered mines and booby traps
12. Received sniper or sapper fire
13. Unit patrol ambushed
14. Flew in aircraft (fixed wing or helicopters) and was shot down
15. Engaged VC and/or NVA in firefight
16. Saw Americans killed, and/or saw Vietnamese killed
17. Wounded
18. Captured by the enemy

Violence during Pregnancy and Substance Use

HORTENSIA AMARO, PHD, LISE E. FRIED, MSPH, HOWARD CABRAL, MPH, AND BARRY ZUCKERMAN, MD

Abstract: Violent incidents were assessed as part of a prospective study of 1,243 pregnant women. Participants were predominantly poor, urban, minority group women. Seven percent (n = 92) of women reported physical or sexual violence during pregnancy. Most of the women (94 percent) knew their assailant. Victims of violence were at greater risk of having a history of depression and attempted suicide, having more current depressive symptoms, reporting less happiness about being pregnant, and receiving less emotional support from others for the current pregnancy. Comparisons of victims and non-victims showed that victims were more likely to be users of alcohol and drugs. In addition, partners of victims were more likely to use marijuana and cocaine. When possible confounders were controlled using multivariable analyses, a woman's alcohol use during pregnancy and her partner's drug use were independently associated with an increased risk of being a victim of violence during pregnancy. Results of this study highlight the importance of assessing exposure to violence during prenatal care, especially among women who are heavy users of alcohol or drugs or whose partners use these substances. (*Am J Public Health* 1990; 80:575–579.)

Introduction

A substantial proportion of women in the general population experience abuse and violence.[1–8] Two recent studies[6,7] indicate that 4 to 8 percent of pregnant women experience abuse during pregnancy and that this problem may be largely unreported to health care providers. Since the risk of abuse is higher for women in young adulthood and this time coincides with women's most active childbearing years,[9] the experience of violence and abuse during pregnancy deserves special attention.

In spite of the prevalence of violence experienced by women, and its damaging impact on women's health and mental health, few studies have attempted to identify the factors associated with violence during pregnancy. One such study found little difference between abused and non-abused pregnant women in race, age, marital status, employment or educational status.[6] Another study[7] found that, compared to non-abused women, women who experienced abuse during pregnancy were of lower socioeconomic status, higher parity, more likely to be single, and had a history of depression or other psychiatric symptoms. Abused women were also more likely to report alcohol use, and a trend in the data indicated that they may also have higher levels of illicit drug use.[7] While this preliminary finding is consistent with previous associations between alcohol and drug use and family violence in the general population,[8] methodological problems such as small numbers of abused women in the sample and reliance on self-reported drug use[10] limit firm conclusions about the role of these factors during pregnancy.

The aims of the present analysis are: to describe the prevalence and patterns of violent incidents during pregnancy; to describe the association between demographic and psychosocial characteristics and violence during pregnancy; to investigate the association between the experience of violence during pregnancy and the use of alcohol and illicit drugs by pregnant women and their partners; and to investigate the association between the experience of violence during pregnancy and newborn outcomes.

Methods

Sample Recruitment

Subjects were consecutively recruited from July 14, 1984 through June 30, 1987 in the Women's and Adolescent Prenatal Clinics of Boston City Hospital. Eligible subjects were English- or Spanish-speaking women who were willing to give informed consent for study participation. The protocol was approved by the Human Studies Committee of Boston City Hospital. Subjects were protected from the use of data for criminal prosecution by a Writ of Confidentiality obtained under Title 42 of the United States Code Section 242A.

Assessment of Participants

All participants were interviewed during the prenatal and postpartum period by a trained bilingual interviewer. To minimize attrition, participants were paid $10 for each interview. The first interview assessed violent incidents occurring in the time period from three months prior to the calculated day of conception through the day of the interview. The postpartum interview determined violent incidents from the time of the previous interview through the time immediately prior to the delivery of the baby. Violent incidents were ascertained by asking the following question, "Were you physically threatened or abused, or were you involved in any fights or beatings?" The respondents were then asked to "describe what happened," and probed to find out whether the assailant was known to the victim, the type of injury, whether they had seen a doctor, and whether they were hospitalized overnight. Victims of violence were defined as those women who experienced physical or sexual violence during their pregnancies. Verbal threats or emotional abuse were not included as an episode of violence in this analysis.

A close-end, forced-choice interview elicited sociodemographic characteristics and the timing and frequency of the use of cigarettes, alcohol, marijuana, cocaine, and other illicit psychoactive substances prior to and during pregnancy. Data on drug and alcohol use were obtained for the same time periods as were data on episodes of violence. Participants were asked to furnish urine samples at the time of each interview and were informed that their urine would be assayed for "marijuana metabolites and prescription and nonprescription drugs," but that these results would remain confidential and not become part of their clinical record. The

This paper, submitted to the Journal February 3, 1989, was revised and accepted for publication November 21, 1989.

© 1990 American Journal of Public Health 0090-0036/90$1.50

use of other substances such as alchohol and other drugs was ascertained by self-report alone. Urine assays were conducted by Enzyme Mediated Immunoassay Technique (EMIT),[11] and positive results were confirmed by Mass Spectrometry/Gas Chromatography for cocaine metabolites and by High Pressure Liquid Chromatography[12] for marijuana metabolites. Use of these drugs was determined by both positive self-report or positive urine assay. A full description of the procedure for the urine assays has been published elsewhere.[13]

During the prenatal interview, respondents were also asked to report whether their partners used alcohol, marijuana or cocaine. Quantity measures of partner's drug use were also asked but proved to be difficult for the women to answer and were therefore not included in the analysis.

Life stress was measured by the Life Experiences Survey (LES) whose reliability and validity has been demonstrated.[14] For this analysis, life stress was measured by the Negative Life Events subscale of the LES, which is a summary scale of the number and negative effect of life events experienced in the past year.

Depressive symptoms were measured by the Center for Epidemiological Studies—Depression Scale (CES-D)[15] whose validity and reliability for the CES-D have been demonstrated and reported.[15–22] Past history of depression and suicide were measured by asking respondents, "In your lifetime, have you had two weeks or more during which you felt sad, blue, depressed, or when you lost all interest and pleasure in things that you usually cared about or enjoyed?" History of suicidal feelings and attempts were assessed by asking "Has there ever been a period of two weeks or more when you felt like you wanted to die?" and "Have you ever attempted suicide?"

Following delivery, trained record reviewers, without knowledge of the hypotheses of this analysis, abstracted medical records using a precoded protocol, which documented participants' reproductive and general medical health histories.

Statistical Analysis

Odds ratios and 95% confidence intervals (CI) were used to compare victims of physical or sexual violence during pregnancy to non-victims of violence on demographic, medical and psychosocial characteristics and on drug and alcohol use.[23] Least square multiple regression was used to determine the association between neonatal growth parameters and violence during pregnancy while controlling for potentially confounding variables.[24] Multiple logistic regression was used to assess the multivariable relationship between violence and drug use. Adjusted odds ratios and 95% CI were calculated from this model.[23]

Results

Sample Characteristics

Eighty-six percent of 1,932 eligible women participated in the study; 144 (8 percent) refused to participate and 124 (6 percent) who had agreed to participate left after the prenatal clinic visit prior to the interview. Non-participants were more likely than participants to be White (19 vs 9 percent), older (26 years vs 24 years), cigarette smokers (41 vs 34 percent) or third trimester registrants (40 vs 22 percent). The two groups were similar in parity, use of alcohol, marijuana, cocaine, or other drugs.

Seventy-eight percent (n = 1,303) of the women who were recruited completed the study. Of the 361 women who were lost to follow-up, most (81 percent) delivered in another hospital or had an elective abortion. Sixty (5 percent) of the 1,303 who completed the study were excluded from the analysis because of a missing medical record review or infant examination, leaving 1,243 completed cases. Completed cases (n = 1,243), when compared to those lost to follow-up or with incomplete infant data (n = 421), had similar sociodemographic characteristics and similar patterns of alcohol, marijuana, cocaine, and other drug use.

The sample of 1,243 participants with complete data reflects the low income (48 percent with household income ≤ $500 a month), predominantly ethnic minority (North American Black = 55 percent, foreign-born Black = 19 percent, Hispanic = 18 percent, White = 8 percent), single (62 percent), and primiparous (55 percent) population served at the prenatal clinic. While 16 percent of the participants were less than 18 years old, 66 percent were between 19–29 years of age.

Violence during Pregnancy

Seven percent (n = 92) of women in the study reported physical or sexual violence during pregnancy. An additional 3 percent of the study population (n = 37) reported incidents of violence in the three months prior to the pregnancy but not during their pregnancy. Less than one percent (n = 11) of women in the sample (12 percent of victims) reported incidents both three months before and during pregnancy.

Sixty percent of the victims were subjected to one incident of violence during pregnancy, 25 percent were victimized twice and 15 percent experienced three or more incidents. More incidents occurred in the first trimester (55 percent) than in the second (40 percent) or third trimesters (25 percent). Most of the women (94 percent) knew their assailant. Thirty-six percent of the victims saw a doctor for at least one of the violent incidents during pregnancy and 10 percent were hospitalized overnight as a result of one of these incidents.

Comparison of Victims and Non-Victims

Compared to non-victims (Table 1), victims had higher relative odds of identifying themselves as White (7 vs 15 percent), born in the US (65 vs 76 percent), and single (62 vs 75 percent). They were also more likely to be on Medicaid (60 vs 76 percent), to have had a history of sexually transmitted diseases (17 vs 30 percent) and to have had an elective

*Syphilis, gonorrhea, herpes, pelvic inflammatory disease, chlamydia

abortion (38 vs 50 percent). The two groups had similar levels of educational attainment (42 percent of victims had 12 years of school vs 39 percent of non-victims), mean ages ($x = 24$ for each group), employment status (24 percent not employed in each group) and parity (53 percent of victims were primiparas vs 52 percent of non-victims).

Victims of violence differed from non-victims on a number of psychosocial measures (see Table 2). Compared to non-victims, victims were at greater risk of having reported a history of one or more depressive episodes (33 vs 56 percent) and to have attempted suicide (5 vs 17 percent), reporting unhappy feelings about their current pregnancy (20 vs 33 percent), perceiving their partners (11 vs 22 percent) and families (14 vs 27 percent) as unhappy about their pregnancy, and feeling a lack of support during their pregnancy (13 vs 36 percent). Victims reported more depressive symptoms (mean difference = 5.6, 95% CI = 3.35, 7.86) and greater numbers of negative life events in the past year (mean difference = 13.16, 95% CI = 10.01, 16.31).

These demographic and psychosocial characteristics did not differ between women who experienced one compared to two or more incidents of abuse during pregnancy (data available on request to authors).

Drug Use among Victims and Non-victims

Women were divided into three categories (nonusers, light users, and heavy users) based on their frequency of use and the number and type of different drugs used during pregnancy. Since we have shown that among marijuana and cocaine users, a positive urine assay is associated with more frequent drug use,[13] we designated women who had a positive urine for either drug and those who self-reported using opiates and/or marijuana or cocaine at least weekly during pregnancy as heavy users. Users of any illicit drug who did not meet the heavy use criteria were categorized as light users.

Victims of violence during pregnancy were at greater risk than non-victims of being heavy users of alcohol (OR = 2.43, 95% CI = 1.71, 3.46) and illicit drugs (OR = 2.68, 95% CI = 1.72, 4.17). A comparison of frequency of use by victims and non-victims showed that victims were heavier substance users in all categories of use than non-victims (see Table 3).

Compared to non-victims, women who were victims of violence had greater odds of having a male partner who was a marijuana (OR = 2.27, 95% CI = 1.46, 3.53) and/or cocaine (OR = 2.35, 95% CI = 1.81, 4.48) user. Further, odds ratios demonstrate a two-fold increase in the use of two or more drugs (OR = 3.2, 95% CI = 1.92, 5.48) by partners of victims when compared to partners of non-victims. Alcohol use by partners was not an increased risk for victims (OR = 1.03, 95% CI = 0.63, 1.69).

Alcohol and drug use did not differ between women who experienced one versus two or more incidents of abuse during pregnancy (data available on request to authors).

A multiple logistic regression (Table 4) shows that the risk of being a victim of violence was associated with a woman's alcohol use during pregnancy and drug use by her partner even when controlling for race, age, marital status, education, and history of violence in the three months prior to pregnancy. While heavy drug use during pregnancy (use of opiates or weekly use of marijuana or cocaine or positive urine assay) was associated with a 39 percent increase in the odds of being a victim of violence, chance cannot be ruled out as the explanation for this finding. Violent incidents in the three months prior to pregnancy have strong predictors of violence during pregnancy.

Birth Outcomes

Multivariable regression analyses were conducted in

TABLE 2—Relative Odds of Selected Psychosocial Differences of Victims of Violence Compared to Non-victims (n = 1,243)

Variable/Comparison	Relative Odds	95% Confidence Interval

Violent incidents—3 months prior to pregnancy	5.87	(2.73,12.60)

order to investigate the relationship between violence during pregnancy and birthweight, infant length, head circumference, and gestational age. Each regression model included ethnicity, age, pre-pregnancy weight, weight gain during pregnancy, parity, number of prenatal visits, history of sexually transmitted diseases, marijuana use, cocaine use, alcohol use, opiate use, and cigarette use. Once confounders were controlled, the association of violence to birth outcomes, while generally in the expected direction, was weak: birthweight: −19 g, (95% CI = −115, 78); length: 0.15 cm, (95% CI = −0.68, 0.38); head circumference = −0.14 cm, (95% CI = −0.48, 0.19); gestational age: 0.13 weeks, 95% CI = −0.29 to 0.55).

Discussion

The findings of this study support previous reports on the prevalence of violence during pregnancy.[6,7] Of greater importance are the results which provide evidence of a strong relation between violence during pregnancy and the use of alcohol by the pregnant woman and the use of illicit drugs by her male partner.

A number of previous studies have shown that abused women are at greater risk of using heavier quantities of alcohol and prescription and non-prescription drugs than women who are not abused.[4,7] While the cause and effect relationship between use of alcohol and experience of violence is unclear, there are indications that women who are abused may self-medicate with alcohol, illicit drugs, and prescription medication in order to cope with the violence.[4,5,25] For example, in a review of medical records, Stark, *et al*,[4] determined that increased alcohol and drug use followed the first incident of abuse.

The relation between the male partner's drug use and violence during pregnancy has not received as much attention. In general, among men who batter their female partners, substance use has been found to frequently accompany battering.[7,26–28] One author[29] has suggested that drinking is used by men who batter to disavow their violent behavior and disclaim responsibility for their actions. Findings from the present study indicate that multiple drug use among male partners is independently associated with over a two-fold increase in women's experience of violence during pregnancy. Since this study did not directly investigate whether the assailant was the male partner, it is not possible to identify the perpetrator of violence as the male partner. Anecdotal evidence from the interviews suggests that a large proportion of the perpetrators were male partners, however. Further research is needed to determine whether the use of illicit drugs actually promotes violent behavior, is employed as a culturally sanctioned justification for engaging in violence without taking responsibility for it, or is associated through some third causal factor to violence.

The results of this study indicate that once sociodemographic factors and drug use are taken into account, the experience of violence during pregnancy is weakly, if at all, associated with newborn size or gestational age. It is possible that infrequent but severe injuries are associated with adverse pregnancy outcomes. However, the small number of women reporting such injuries did not allow us to assess this possibility.

A number of important limitations should be considered when interpreting the results of this study. First, the subjects were primarily poor, Black, and Hispanic women living in the inner-city. The prevalence of violence and drug use in other populations may be different. Second, our assessment of abuse was limited because it did not evaluate the full psychological impact of an abusive relationship that typically involves a climate of threat and fear. Third, the assessment of violence through limited questions about current experiences of violence does not allow for an understanding of the causal ordering of the relationship between violence, drug use, and depression. Finally, validity of the assessment of the male partner's drug use may be reduced since it was conducted through the female participant, rather than through direct self-report and/or urine assay from the male partner.

With these limitations in mind, prenatal health care providers should assess women's exposure to violence prior to and during pregnancy. In addition, assessment of psychoactive drug use among women and their partners is critical, since such behaviors may be employed as a marker for risk for violence during pregnancy. Further, the possibility of continued violence against a woman after delivery and the potential extension of this violence to the child have important public health implications. Since violence and drug use reflect a wider set of environmental conditions and psychosocial factors that create a context that is detrimental to a mother's and infant's physical and mental health, prevention and intervention efforts will need to be set within a framework of services to address these needs. Training of health care professionals about the problems of drug abuse and family violence is a critical and necessary first step in early identification and intervention efforts.

ACKNOWLEDGMENTS

This work is supported by grants from the National Institute of Drug Abuse (NIDA-R01DA03509), the Bureau of Health Care Delivery and Assistance, Maternal and Child Health Branch (Grant #MCJ-009094) and the Harris Foundation. The authors would like to acknowledge Gabrielle Lopez, Elva Perez Trevino, Claudia Caicedo, Julie Skoler, and Isolde Goernemann for conducting the interviews, Laura Hennigan for laboratory analyses, Julie Johnson and Michael Winter for data processing, and Rose Dobosz for tracking and coding the data. We also thank Elaine Carmen, MD, and Maria Aguiar-Morrison, MPH, for their helpful comments.

The findings were presented at the American Public Health Association 116th annual meeting, November 1988 in Boston, Massachusetts.

NCI Announces Research Opportunities in Cancer Prevention

The Division of Cancer Prevention and Control (DCPC) of the National Cancer Institute has announced it is accepting applications for the next Cancer Prevention Fellowship Program. Funding permitting, as many as 10 fellows will be accepted for up to three years of training, beginning July 1, 1991. The *deadline* for applications is September 1, 1990.

The purpose of this program is to attract individuals from a multiplicity of health science disciplines into the field of cancer prevention and control. The program provides for:

- Participation in the DCPC Cancer Prevention and Control Academic Course;
- Working at NCI directly with individual preceptors on cancer prevention and control projects;
- Field assignments in cancer prevention and control programs at other institutions.

Benefits include selected relocation and travel expenses, paid federal holidays, and participatory health insurance. Those eligible for the program include those with MD or DDS degree from a US, territorial, or Canadian medical school. Foreign medical graduates must have current ECFMG/FMGEMS certification and appropriate experience (e.g., one year residency) in a training program approved by the Accreditation Council for Graduate Medical Education. Also eligible are those with PhD, DrPH, or other doctoral degree in a related discipline (epidemiology, biostatistics, and the biomedical, nutritional, public health or behavioral sciences). Foreign education must be comparable to that received in accredited US, territorial, or Canadian institutions. Applicants must be US citizens or resident aliens eligible for citizenship within four years.

For more details and application catalog, send a postcard or letter with your name and home address to: Douglas L. Weed, MD, MPH, PhD, Director, CPFP, DCPC, National Cancer Institute, Executive Plaza South, T-41, Bethesda, MD 20892. Further inquiries should be directed to Barbara Redding at NCI; (301) 496-8640 or -8641.

Risk Factors for Depressive Symptomatology in a Drug Using Population

JOHN C. BUCKNER, PHD, AND WALLACE MANDELL, PHD, MPH

Abstract: This study employs a prospective design to examine possible personality, drug use, stressful life event, and social support-related variables associated with the onset of a depressive episode in a cohort of psychoactive drug using young adults. Two waves of data, collected one year apart, were available on 942 individuals. Cases (n = 62) were free of depressive symptoms at time 1 but reported significant symptomatology at time 2 as measured by the depression subscale of the Brief Symptom Inventory. Controls (n = 490) were those free of depressive symptoms at both time points. In multivariate analyses, users of the central nervous system depressant methaqualone had a nearly four-fold elevated risk for depressed mood as compared to nonusers. Additional risk factors significant after multivariate adjustment included lower self-esteem at time 1 and negative life events. These results highlight the multifactorial nature of depressive symptomatology. (*Am J Public Health* 1990; 80:580–585.)

Introduction

Using predominantly case-control comparisons on general population samples, the association between negative life events,[1–9] lack of social support,[10,11,4,5,8,12] and self-esteem[13–18] with depressive symptoms and disorder has been well documented. Analogous prospective studies are rare.[17] While research has documented an association between alcohol use and depression,[19–21] much less is known about the potential effects of other drugs or about the relative and possibly interactive effects of life events and drug use on depression symptomatology. One obstacle to such studies is the low base rate of negative life events and/or heavy substance use in most samples making it unfeasible to examine their relationships. By focusing on a population of young adults who frequently use a variety of psychoactive substances, we estimated the adjusted relative risk of various drug use, personality, psychosocial, and negative life event variables for developing an episode of depressed mood.

Methods

We utilized a case-control methodology nested within a prospective study[22,23] to investigate risk factors for depressed mood using data from a study on the consequences of arrest for marijuana possession, a short-term longitudinal investigation of drug using young adults.*

Study Population

In 1981–82, 1,134 adults living in the State of Maryland were interviewed and 942 were relocated and agreed to a reinterview one year later. A primary aim was to evaluate the effects of having been arrested and tried for marijuana possession on subsequent drug use and mental health. An application for a certificate of confidentiality, which protects the identity of research study subjects, was approved by the US Secretary of Health and Human Services. Written consent was obtained of all research participants and each individual was informed as to the nature of the study and the certificate which protects the information they provide from seizure by police or use in any civil or criminal proceeding.

The panel of 942 individuals which forms the basis of the present study was comprised, in part, of a random sample of 621 individuals, stratified by month of arrest, from a roster of all adults who had been tried in 1981 for marijuana possession within the district courts of Maryland. An additional 321 non-arrested individuals, nominated by their arrested counterparts as being friends or acquaintances, were selected as a neighborhood-based comparison group. This nomination procedure was done to ensure comparability between the two groups on demographic characteristics and drug use patterns.

Operationalization of Variables

The presence of depressive symptomatology in the week prior to interview was assessed using the depression subscale of the Brief Symptom Inventory (BSI)—the short form of the Symptom Checklist-90 (SCL-90).[24,25] Internal consistency analysis of the depression sub-scale revealed coefficient alpha = .78 at the time of first interview (Time 1) and alpha = .80 at the second interview (Time 2). The depression subscale, consisting of six items, has been found to correlate (.95) with its corresponding longer version on the SCL-90.[25] There is evidence in support of the temporal stability and the convergent and discriminant validity of the BSI depression subscale.[26]

Individuals were classified as a case if they did not report depressive symptoms at Time 1 but reported symptoms at Time 2 that placed them in the 90th centile or above on the non-patient norms for the BSI depression subscale.[26] This cut-point was selected to serve as a strong contrast between cases and controls while still retaining a sufficient sample size for purposes of statistical power. While this depression measure does not identify a case of dysthymia or major depressive disorder according to DSM-III-R[27] criteria, an individual defined as a case in this study would present clinically with at least moderate symptoms of depression. All individuals who reported no or minimal symptoms of depression at both time points were selected to form a control group. Using these criteria a total of 62 cases and 490 controls were selected. Individuals excluded from analyses were those who reported mild-to-severe depressive symptoms at Time 1. Inspection of the depression scores at both time points revealed that those selected as cases went, on average, from the 50th percentile at Time 1 to the 95th percentile at Time 2. In contrast, those selected as controls were at about the 45th percentile at Time 1 and remained there at Time 2.

The wording of the BSI allowed for a determination of the current level of depressed mood experienced by a study participant, although, it could not help determine depressed

mood in the months prior to each administration. While an imperfect and somewhat less specific measure for determining case status than use of an instrument such as the Diagnostic Interview Schedule,[28] it is unlikely that a bias was produced by this manner of case-control selection. Because the BSI was administered at Time 1, some control for prior depressed mood was achieved; more than is the case in many other case-control comparisons.

Participants were asked about frequency of use of a wide variety of licit and illicit drugs in the two months prior to each interview. Alcohol and marijuana were used with enough regularity to justify coding on an interval level (3 = daily; 2 = two–three times a week; 1 = one time a week or less; 0 = no use). Tobacco use was measured in packs of cigarettes smoked per day. The vast majority of use of such substances as amphetamines, barbiturates, methaqualone (Quaalude, Sopor), cocaine, heroin, hallucinogens, and anxiolytics (e.g., Valium, Librium) occurred on a weekly or less frequent basis. Therefore, these drug variables were dichotomously coded with 1 representing any reported use of the drug during the two months prior to interview and 0 indicating no use.

The occurrence of any of five negative stressful life events (arrest, conviction, hospitalization, traffic accident, fired from job) in the 12 months between interviews was assessed and a summative count score was created. Prior research has shown that weighting of events before creation of an overall score does not increase prediction of the dependent variable.[29-32] These negative life events are typical of those found on life event inventories[33] and represent life stressors that occur with relative frequency in this population.

Separate questions tapping perceived social support, or social embededness,[34] with family members and with peer group were asked of all respondents at both interviews: "Do you feel a sense of solidarity, closeness, belonging to your family?" Four dichotomous variables were created from the Time 1 and Time 2 questions representing perceived social embededness with family or friends or lack of support/embededness. The presence of a spouse or living together with a partner was also determined and dichotomously coded as another important indicant of social support.[32,35]

Finally, the Rosenberg Self-Esteem Scale,[36] a widely used 10-item measure of self-esteem, was administered at both interviews. Extensive research has demonstrated the predictive and construct validity of this instrument.[37] With the present sample, the instrument displayed good internal consistency (Coefficient alpha = .75) and the one year test-retest stability was r(938) = .49.

Univariate logistic regression models that estimate the crude relative risk ratio for the development of an episode of depression were first calculated for variables from each of the demographic, drug use, life events, social support, and personality domains. Using multivariate logistic regression techniques, variables predictive of case status in univariate analyses were simultaneously evaluated to estimate adjusted relative risks. The presence of multiplicative interaction was examined for pairwise combinations of variables that remained significant in the multivariate analysis.

Results

Descriptive statistics for the 62 depressed mood cases and 490 controls and crude relative risk estimates based on univariable logistic regression analyses are presented in Table 1 for categorical variables and Table 2 for variables measured on a continuous scale. Cases were fairly similar to controls with respect to age, race, sex, marital status, being employed or in school, recent history of marijuana arrest, and socioeconomic status (not shown in tables). Univariate relative risk (RR) estimates for the development of depressive symptomatology were found for any use during the two months prior to the second interview for methaqualone, anxiolytics, and less strongly for heroin, tobacco, and hallucinogens.

TABLE 1—Estimated Relative Risk for an Episode of Depressed Mood Based on Univariate Logistic Regression Analysis with Categorical Variables

Variables	Cases No. (%) (N = 62)	Controls No. (%) (N = 490)	Referent Category	Relative Risk Estimate (unadjusted)	(95%CI)	p value
Sociodemographic						
Male	52 (84)	382 (78)	female	1.47	(.72, 2.99)	.29
White	24 (39)	166 (34)	black	1.23	(.72, 2.12)	.45
Employed or in school	40 (65)	322 (66)	no	.94	(.54, 1.64)	.84
Recent marijuana arrest	45 (73)	321 (66)	no	1.39	(.77, 2.51)	.27
Drug Use						
Amphetamines (Time 1)	7 (11)	49 (10)	no use	1.15	(.49, 2.65)	.75
Amphetamines (Time 2)	9 (15)	52 (11)	no use	1.43	(.67, 3.06)	.36
Barbiturates (Time 1)	5 (8)	32 (7)	no use	1.26	(.47, 3.35)	.65
Barbiturates (Time 2)	6 (10)	28 (6)	no use	1.77	(.70, 4.45)	.3
Methaqualone (Time 1)	4 (6)	31 (6)	no use	1.02	(.35, 2.99)	.97
Methaqualone (Time 2)	10 (16)	23 (5)	no use	3.90	(1.76, 8.65)	.0008
Anxiolytics (Time 1)	3 (5)	29 (6)	no use	.81	(.24, 2.74)	.73
Anxiolytics (Time 2)	8 (14)	26 (5)	no use	2.64	(1.14, 6.12)	.02
Cocaine (Time 1)	16 (26)	96 (20)	no use	1.43	(.77, 2.63)	.25
Cocaine (Time 2)	14 (23)	99 (20)	no use	1.15	(.61, 2.17)	.66
Hallucinogens (Time 1)	6 (10)	26 (5)	no use	1.91	(.75, 4.84)	.17
Hallucinogens (Time 2)	7 (11)	25 (5)	no use	2.37	(.98, 5.73)	.06
Heroin (Time 1)	4 (6)	16 (3)	no use	2.04	(.66, 6.32)	.21
Heroin (Time 2)	7 (11)	24 (5)	no use	2.47	(1.02, 6.00)	.046
Social Support (Time 2)

Self-esteem (Time 2)	3.08 (.45)	3.46 (.42)	.14	(.07, .26)	<.0001
Life Events: (count 0–4)					
Negative Events	.79 (.91)	.44 (.72)	1.67	(1.24, 2.26)	.0009

*These frequency codes range from 0–3: (0 = no use; 1 = 1 time a week or less; 2 = 2–3 times a week; 3 = daily use).
**These frequency codes range from 1–7: (1 = no use; 2 = >1 cigarette a day, 3 = 1–5 cigarettes a day; 4 = 10 cigarettes a day; 5 = 20 cigarettes a day; 6 = 30 cigarettes a day; 7 = 40 cigarettes a day).

TABLE 3—Estimated Relative Risk for an Episode of Depressed Mood Based on Multivariate Logistic Regression Model with Drug Variables Only

Variable	Referent Category	Estimated Relative Risk	(95%CI)	p value
Drug Use (Time 2)				
Amphetamines	no use	.81	(.29, 2.30)	.69
Barbiturates	no use	.54	(.14, 7.08)	.37
Methaqualone	no use	5.27	(1.86, 14.96)	.002
Anxiolytics	no use	2.07	(.75, 5.71)	.16
Cocaine	no use	.53	(.24, 1.19)	.13
Hallucinogens	no use	2.14	(.77, 6.00)	.15
Heroin	no use	3.32	(1.18, 9.30)	.02
Alcohol frequency	NA*	1.06	(.79, 1.43)	.67
Marijuana frequency	NA*	1.07	(.82, 1.40)	.59
Tobacco frequency	NA**	1.08	(.93, 1.25)	.34

*Not applicable. These frequency codes range from 0–3: (0 = no use; 1 = 1 time a week or less; 2 = 2–3 times a week; 3 = daily use).
**Not applicable. These frequency codes range from 1–7: (1 = no use; 2 = >1 cigarette a day; 3 = 1–5 cigarettes a day; 4 = 10 cigarettes a day; 5 = 20 cigarettes a day; 6 = 30 cigarettes a day; 7 = 40 cigarettes a day).

To statistically control for multiple drug use, a multivariate logistic regression model containing main effect terms for all Time 2 drug variables (see Table 3) was created. The relative risk estimates show a clear excess risk for those reporting any use of methaqualone in the prior two months (RR = 5.27; 95% CI = 1.86, 14.96) as well as those reporting any use of heroin (RR = 3.32; 95% CI = 1.18, 9.30). Two-way interaction terms were then evaluated for methaqualone and heroin with combinations of the other drug variables. None were found to be statistically significant at ($p < .05$) although the interaction term for methaqualone and barbiturate use was significant at ($p < .10$) and was further evaluated in subsequent analyses.

Crude relative risk estimates for the life event, social support, and self-esteem measures are apparent in Tables 1 and 2. Higher levels of self-esteem at Time 1 appear to act as a protective factor with the risk of depressed mood dropping by an estimated .32 (95% CI = .17, .59) with each unit increase in self-esteem. Conversely, individuals with lower levels of self-esteem appear more vulnerable to the development of an episode of depressed mood. A strong cross-sectional relationship between Time 2 self-esteem and depression was also present. Negative life events happening in the year before follow-up served to elevate the risk for depression with each occurrence of such an event (arrest, conviction, fired from job, or hospitalization) increasing the risk for developing depressed mood 1.67-fold (95% CI = 1.24, 2.26). Risk for depressed mood was less if the subjects reported that they felt embedded within their family (RR = .41; 95% CI = .19, .91) or within a peer group (RR = .47; 95% CI = .27, .85). Being married or living with someone was not associated with case-status.

In a multivariate logistic regression model (see Table 4) containing main effect terms for life events, social support and self-esteem, the relative risk estimate for family as well as for peer group embededness were sharply reduced suggesting that the univariate relationships were due to associations with other variables. Self-esteem at the earlier period and the occurrence of negative events during the year remained strong predictors of case status. All possible two-way interactions among statistically significant variables in this model were tested but no interaction was detected.

We then tested a multivariable function (table not shown) that combined the drug use and psychosocial varia-

TABLE 4—Estimated Relative Risk for an Episode of Depressed Mood based on Multivariate Logistic Regression Model with Social Support, Self-esteem, and Negative Event Variables Only

Variable	Referent Category	Estimated Relative Risk	(95%CI)	p value
Family embededness (yes)	no	.50	(.21, 1.16)	.11
Peer group embededness (yes)	no	.58	(.35, 1.22)	.18
Self-esteem (Time 1)	NA*	.39	(.21, .75)	.005
Negative events	NA**	1.60	(1.15, 2.15)	.005

*Not applicable. This variable is measured on a continuous scale.
**Not applicable. This variable ranges from 0–4 and was not categorized.

bles that had retained p values of .05 or less in the prior multivariate models as well as the interaction term for methaqualone and barbiturate use. The prior association between heroin use and depressed mood no longer held in this model nor did the methaqualone-barbiturate interaction term. Negative events, self-esteem, and methaqualone use maintained their independent effects. A final model was tested that retained these three main effect terms and produced the following estimates: negative events (RR = 1.45; 95% CI = 1.06, 2.00); self-esteem (RR = .32; 95% CI = .17, .59); and methaqualone use (RR = 3.70; 95% CI = 1.59, 8.63). Interaction was not detected among pairwise combination of these three variables.

Discussion

Prior research evidence has suggested associations between self-esteem, the occurrence of negative life events, and indices of social support with depressed symptomatology. With the exception of social support, which only evidenced a trend in the predicted direction in multivariate analysis, this was corroborated in our findings; and, importantly, our results indicate that, when controlling for each other, these variables remain independent predictors for who will develop a new episode of depression. It is conceivable that a more refined measure of social support than the ones used in this study might have detected a support-depression association in multivariate, not just univariate, analyses. The measure of life events was limited by the available data to a count of five negative occurrences (arrest, conviction, hospitalization, traffic accident, fired from job). A more exhaustive index of life events would likely have produced an even stronger association.

This study has documented that a similar pattern of risk factor relationships for depressed affect exists among a sample of psychoactive drug users as has typically been found in general population samples.[1–9,15,17] The final model suggests that individuals who have low self-esteem (measured a year prior), or who experience negative life events, or who use methaqualone, are at elevated risk for developing depressed mood. An issue to consider was the effectiveness of the nested case-control design in controlling for Time 1 depressed mood. We examined this by re-analyzing all models reported in Tables 1–4 and the final model. While the Time 1 measure of depressed mood was a strong predictor of the same variable at Time 2, the same findings emerged from the reanalysis with only slight and trivial changes in the relative risk estimates. Thus, sufficient control for prior depressed mood appears to have been achieved in the design alone.

In this sample, methaqualone use appears to substantially increase the risk for depressed symptoms independently of self-esteem or negative life events. The majority of methaqualone users who became depressed at Time 2 may have initiated their use of this substance during the study period: Of the 10 individuals with depressed symptoms who reported use of methaqualone at Time 2, seven (70 percent) had not reported use at Time 1 while three (30 percent) reported use at both time points. This methaqualone-depression association cannot be explained by the potential confounding effects of other drug use assessed in this study or other predictive variables. In fact, the adjusted relative risk estimates for methaqualone use were higher than the crude estimate. Nevertheless, the existence of a third variable which causes both a propensity to use methaqualone and to become depressed cannot be ruled out. When examined with other drug variables, heroin use was also related to depression. However, when considered together with psychosocial variables, heroin use failed to retain its importance in predicting an episode of depression.

Our review of the literature indicates that the association found between methaqualone use and depressed mood in this drug using sample is a new finding and, therefore, deserves further comment. Methaqualone is a synthetic central nervous system depressant compound that is similar to barbiturates in its sedative and hypnotic action.[38,39] Until January 1984, when it was made a controlled substance,[40] the drug was marketed in the United States under the trade names Quaalude, Sopor, Parest, Optimil, and Somnafac.[41] Its use reached epidemic proportions in the 1970s and early 1980s [42–46]; perhaps, due in part to its purported aphrodisiac qualities.[47] Although its use today has diminished as a result of discontinuation of legal production in the United States,[48] quantities produced by clandestine domestic or small foreign laboratories are still available.[47,48]

Methaqualone users are reported to be more likely to also use other illicit and licit psychoactive substances than are non-users of the drug.[44,49] This was confirmed in the present sample. The multi-drug involvement of methaqualone users could account for this study's finding of univariable associations between depressed mood and various other substances (marijuana, tobacco, hallucinogens) but lack of association when controlling for methaqualone use. Our results suggest the possible prudence of adjusting for the potential influence of methaqualone use when examining the relation between other drugs and depression.

A relation between methaqualone use and depressed symptomatology has been hinted at in two prior studies. Schwirian and colleagues,[49] in a study of personality characteristics of methaqualone users, noted a cross-sectional association between duration of methaqualone use and mea-

sures of "lethargy and introspectiveness." Craig and Van Natta[50] looked at cross-sectional, unadjusted associations between recent use of a variety of prescription medicines and the Center for Epidemiologic Studies' depression (CES-D) scale. Users of anxiolytics and sedatives (which included but were not limited to methaqualone) had significantly greater proportions of high CES-D scores than did non-users of either class of drugs with stronger associations for females than for males. Barbiturates, a class of drugs with a similar sedative-hypnotic action to methaqualone, have also been linked to depression. Recent case reports indicate that phenobarbital may cause severe depression in patients taking the drug to control seizure disorders.[51,52] At a more general level, Judd and Grant[53] found that central nervous system depressant users, especially sedative users, displayed pronounced neuropsychological deficits on cognitive tasks which assessed abstract thinking, nonverbal learning, eye-hand coordination, and perceptual accuracy.

The temporal ordering of methaqualone use and depressed mood is important in terms of etiology. In a survey of college student methaqualone users that is relevant to this issue, Kochansky and colleagues[44] report that while no particular emotion encouraged the use of methaqualone, "moods named as clearly aversive to use were depression and anger." This study suggests that use of methaqualone is more likely to be an antecedent of depressed mood than a consequence. Until more conclusive research is conducted, it would be premature to infer that methaqualone use causally contributes to the development of depressed mood. Also, it should be noted that methaqualone is an infrequently used drug. Therefore, despite the almost four-fold relative risk for depressed mood, its attributable risk both in the general population and among drug user samples would be less than that of other explanatory variables including other potential etiologic factors examined in this study.

In this sample, lower self-esteem was associated with the development of a depressive episode one year later regardless of drug use behavior or the occurrence of negative life events. Likewise, the occurrence of negative life events also independently predicted depressed mood. Such findings may suggest alternative pathways to depressed mood in drug users, with those individuals low in self-esteem, or who use methaqualone, or who experience one or more stressful life events at higher risk. A combination of these risk factors would appear to increase risk in a multiplicative manner. Each one of these three variable's ability to predict subsequent depressed affect does not depend on a particular level of the other two; that is, effect modification was not detected.

A study limitation was reliance on a measure of depressed symptomatology as opposed to a diagnostic classification for depressive disorder. Nevertheless, a strong consistency exists between psychosocial risk factors for depressed symptoms and unipolar depressive disorder indicating a possible continuity between these two conditions.[54]

ACKNOWLEDGMENTS

Data collected in this study were funded by a research grant (#R01DA02417) to the second author from the National Institute on Drug Abuse. This work was supported while the first author was a National Institute of Mental Health Postdoctoral Fellow in Prevention Research (training grant #T32MH18834). The authors wish to thank James C. Anthony and Louis Reedt for helpful comments and criticism. An earlier version of this paper was presented at the 117th annual meeting of the American Public Health Association in Chicago, October 22–26, 1989.

European Charter on Environment and Health

Following 12 months of intense diplomatic activity and detailed technical consultations among the 32 countries of the European Region of the World Health Organization, a ministerial conference was held in Frankfurt on December 7–8, 1989, which formally approved a Charter on Environment and Health. The European Region of WHO represents 825 million people and covers an area from Greenland in the west to the Pacific coast of the Soviet Union in the east. The conference was attended by Ministers of both Health and Environment; observers were present from Canada and the United States.

Efforts are underway to secure adoption of the Charter by all sections of society in the countries of the WHO European Region.

The decision to develop the European Charter was based on a growing perception that links between the environment and health were not clearly perceived at international, national, and local levels and that insufficient attention had been given to the integration of health dimensions into policy decisions in such fields as physical planning, energy, transport, and agriculture, nor were potential health consequences always adequately addressed at the planning stage of new developments.

The conference not only addressed specific biological, chemical and physical hazards but placed considerable emphasis on the importance of a salubrious overall environment in terms of housing, the community, and the workplace. In brief, the Charter:

- Acknowledges the dependence of human health on a wide range of environmental factors;
- Devotes a section to entitlements and responsibilities, i.e., of individuals as well as public and private bodies;
- Encompasses principles for public policy—including new policies, technologies and developments—that safeguard the environment and human health;
- Enumerates strategic elements essential to its objectives, i.e., control measures, standards, information systems, and the appropriate use of fiscal/administrative/economic instruments and land-use planning;
- Delineates priority areas to which governments, the European community, and intergovernmental organizations should pay particular attention;
- Lays down steps necessary to reverse negative trends and maintain and increase improvements already taking place, in a section titled "The Way Forward."

A copy of the Charter, as well as a detailed commentary and other relevant materials, may be obtained from the WHO Regional Office of Europe, 8 Sherfigsvej, 2100 Copenhagen, Denmark.

HIV Antibody Testing among Adults in the United States: Data from 1988 NHIS

ANN M. HARDY, DRPH, AND DEBORAH A. DAWSON, PHD

Abstract: Data collected from 21,168 adults using the 1988 AIDS supplement to the National Health Interview Survey were examined to determine awareness of and experience with HIV antibody testing in the United States. Three-fourths of adults knew of the blood test for HIV antibodies; awareness was lower among Blacks, Hispanics, older adults, and those less educated. Overall, 17 percent of adults had been tested; of these, 73 percent because of blood donation, 14 percent through other non-voluntary programs (such as military induction), and 16 percent sought testing voluntarily. While a smaller proportion of Black and Hispanic adults had been tested, they were more likely than their White non-Hispanic counterparts to have been tested voluntarily. Persons who reported belonging to groups with high-risk behaviors were also more likely to have been voluntarily tested. Most of those tested voluntarily received their test results, but only one-third also received prevention information. Three percent of adults plan to be tested voluntarily in the next year; about half will seek testing through their doctor or health maintenance organization. (*Am J Public Health* 1990; 80:586–589.)

Introduction

Counseling and testing for antibodies to human immunodeficiency virus (HIV) are important parts of the US Public Health Service plan for the prevention and control of HIV infection and AIDS (acquired immunodeficiency syndrome).[1] Throughout the United States, confidential and/or anonymous counseling and testing sites have been established to provide these services. Between 1985 and September 1988, over 1.4 million persons were counseled and tested in publicly funded test sites.[2] HIV antibody testing may also be obtained at a variety of other health care settings, but the number tested in these settings is not known. In some instances, such as blood donation and physical examination for military induction, individuals are routinely screened for HIV antibodies.

It is important to have information on the number of persons tested under all the above mentioned circumstances to help evaluate the extent to which these particular prevention strategies have been implemented. To address this need, data were examined on the adult population's experience with the HIV antibody test from the National Health Interview Survey of AIDS Knowledge and Attitudes.

Methods

The National Health Interview Survey (NHIS) is a cross-sectional survey of the US civilian, non-institutionalized population, conducted annually since 1957.[3] Each year, members of 40–50,000 households across the country are interviewed in person by Census Bureau personnel. In addition to basic health and demographic information which is collected every year, supplemental surveys on special health topics which change periodically are also included.

Since August 1987, the NHIS has included a set of questions on AIDS. Data collection with the version of the AIDS survey analyzed in this report began in May 1988 and continued throughout 1988 and 1989. The questionnaire, administered to one randomly selected adult 18 years or older in each family included in the NHIS sample, was designed primarily to estimate adults' knowledge about AIDS, HIV transmission, and prevention of HIV infection. The information obtained has been summarized in previous reports.[4–10] Questions on knowledge about and use of the HIV antibody test are also included in the survey[4–9] and form the basis of this report.

The results are based on interviews conducted from May through October 1988 with 21,168 adults or about 90 percent of eligible respondents. The data were weighted to provide national estimates. These estimates are provisional because the 1988 AIDS records were processed before the other NHIS records and have not yet been merged with them. However, the estimates should differ only slightly from those which will be made using all of the 1988 data. Provisional standard errors for these estimates were calculated by applying a design effect of 1.3 to the standard errors obtained by assuming a simple random sample. These provisional estimates of variance were used to determine the significance of differences observed between proportions; all the differences noted are significant at the 0.05 level.

For analytic purposes, persons tested for HIV antibodies included those who reported they had had their blood tested and those who did not report being tested but who had donated blood since March 1985, when routine screening for HIV antibodies in donated blood began. Information on HIV antibody testing was examined in various demographic subgroups. In addition, two other groups were examined based on information obtained in the survey. The first were persons who reported belonging to one or more of the groups with behaviors associated with an increased risk for acquiring HIV infection (such as men who have had sex with other men or persons who have used illegal drugs by needle). This question is phrased similarly to that used by the Red Cross to screen potential blood donors. Respondents were given a list of statements about risk behaviors and were asked only to indicate if at least one was true for them; they did not indicate which were true. Two percent of respondents reported that at least one of these statements was true. The second group examined included persons who felt they had a high or medium chance of having or getting HIV infection; 3.5 percent of adults fell into this category.

Results

Overall, 75 percent of adults in the US had heard of the HIV antibody test (Figure 1). The percent who were aware of the test varied by age, race/ethnicity, and education, with lower levels of awareness noted among those over 50 years

of age, among Black and Hispanic adults, and among those with less than 12 years of education. People who were more knowledgeable about AIDS and those who reported belonging to one or more of the high-risk behavior groups were more likely to know about the test.

Seventeen percent of adults had been tested for antibodies to HIV (Table 1); the majority because of blood donation since March of 1985. Men were more likely to have been tested than women, Black and Hispanic adults were slightly less likely than White non-Hispanic adults to have been tested. However, Black and Hispanic persons who were tested were more likely to have voluntary testing and testing by other non-voluntary means than their White non-Hispanic counterparts. The group with the highest proportion tested

(35 percent) were those who reported high-risk behaviors for AIDS/HIV and voluntary testing was the most common circumstance for this group.

The characteristics of those tested voluntarily, those tested by all other means (including blood donation), and those not tested are summarized in Table 2. Persons who were tested, regardless of the circumstance were more likely to be younger and better educated than those not tested. Persons tested voluntarily were more likely to be Black and to report high-risk behaviors and a greater chance of HIV infection than those tested under other circumstances and those not tested.

Most (73 percent) of those tested voluntarily were tested only once and 82 percent reported receiving results of their testing. However, of those who got their results, only 32 percent also reported receiving information on how to avoid getting or transmitting HIV.

Six percent of adults planned to be tested in the next year; 45 percent of these had not been tested previously. About half of those with such plans indicated that they would seek testing voluntarily. Figure 2 shows where those with plans for voluntary testing will reportedly go to be tested. Over half (52 percent) will get tested through a doctor or at a health maintenance organization (HMO).

Discussion

Some caution is necessary when interpreting data from the NHIS. While the complex sampling methods used in the survey assure a representative national sample and the response rate to the survey is good, much of the data presented are based on self-report by the participants and cannot be verified. This is especially important when dealing with a sensitive topic such as HIV testing which may affect the person's willingness to respond honestly. However, the figures on HIV antibody testing obtained with the survey have remained relatively stable throughout 1988.[9] Also, the

FIGURE 2—Distribution of Reported HIV Antibody Testing Sites for Those Planning Voluntary Testing in the Future

information on blood donation is consistent with other data on blood donors.[11–13]

In general, awareness of the HIV antibody test is high. However, it is lower than desired in certain important groups such as racial/ethnic minorities. This accounts for at least some of the deficit in testing rates among these groups; when testing rates were examined among those aware of the test, the racial/ethnic differences were smaller and no longer statistically significant. These lower levels of knowledge about the HIV antibody test and lower testing rates for Black and Hispanic adults are particularly important because of the higher rates of AIDS and HIV infection in these two populations.[14] There are also differences in AIDS rates among various subgroups within the Hispanic population.[15] We were unable to examine differences among these various subgroups because of the small numbers in our data set. The same survey instrument will ultimately be used for 20 months (May 1988 through December 1989) making it possible to examine HIV antibody testing experience within Hispanic subgroups in the future. Awareness of the test increased slightly from 1987 to 1988 among adults in the US[6]; however, it remained the same throughout 1988.[9] Efforts to increase the use of HIV antibody testing should also include ways to increase awareness about the test.

As of October 1988, approximately one in six civilian adults had been tested for HIV antibodies, primarily through blood donation. While those with high-risk behaviors who were tested were more likely to be tested voluntarily, 40 percent were tested as a result of blood transfusion. The observation that some individuals with high-risk behaviors for HIV infection have donated blood despite attempts to encourage self-deferral is not new. Further interpretation of these data is limited because the survey was not designed to address this particular issue. First, we have no information on whether any of these high-risk blood donors indicated at the time of their donation that their blood should not be used for transfusion. Thus, we cannot estimate how much of this donated blood was actually transfused. Secondly, we have no information on when these individuals engaged in high-risk behavior or on the specific dates of blood donation. For some of these donors, the high-risk behaviors may have occurred after their donation.

The characteristics of those seeking voluntary testing indicate that a higher proportion were in groups targeted for testing (e.g., those reporting high-risk behaviors) than those tested by other means or those not tested. However, many in these targeted groups have yet to be tested and most of those voluntarily tested perceived themselves to be at low or no risk of having or getting HIV infection and did not report belonging to groups with high-risk behaviors. This may be one reason why a large percentage reported not getting prevention counseling along with their test results. However, counseling is at least as important as testing in helping to prevent the spread of HIV and even low-risk individuals benefit from having such information. Also, some individuals who present for testing may be unwilling to admit risky behavior to health care providers. Post-test counseling on HIV prevention should be provided to all who are tested.

Of those tested voluntarily, 18 percent did not get the results of their tests. This figure includes those who were tested blindly and could not get their results and those who had not yet received their results when interviewed, as well as those who chose not to get their results. Presumably, most were in the latter category, this figure is similar to the 10–20 percent non-return rate reported to the Centers for Disease Control's Counseling and Testing Statistical Reporting System for persons tested at publicly funded HIV counseling and testing sites (K. Cahill, CDC, personal communication). At present the small size of the group who did not get their test results identified in our survey makes it difficult to further characterize them reliably; it will be important to do so in the future when the number of sample cases is larger.

The information on the number who plan to be tested in the coming year can be used to help ensure that the future demand for testing can be met. According to the figures obtained in the survey, approximately five million adults may voluntarily seek HIV antibody testing in the next year. Many of these persons indicated that they would go to their doctor or HMO to be tested. Evidence from other studies suggests that at least some physicians are reluctant to discuss AIDS and associated risk behaviors with their patients.[16,17] Thus, there continues to be a need to educate physicians and other primary health care providers so that they will have the information and skills necessary to provide adequate pre- and post-test counseling for their patients who request HIV testing.

Counseling and testing for antibodies to HIV will continue to be important parts of the effort to control the spread of this infection. The recent recommendation that HIV-infected individuals be immunologically monitored to identify candidates for prophylaxis against *Pnemocystis carinii* pneumonia may lead to an increase in testing.[18] The NHIS AIDS survey will continue to provide a way to monitor the national experience with HIV antibody testing. A public use data tape containing the data collected in 1987 is currently available; the 1988 data tape was to be available at the end of 1989. During 1990, the survey will be expanded to include more questions about HIV antibody testing.

May 7 Designated as National Nurses' Day

Each year, a day is set aside to recognize the outstanding contributions made by the nursing profession. This year, May 7 has been designated "National Nurses' Day" and a nationwide observance will highlight the important work and health care provided by the more than two million registered nurses in the United States. The American Nurses' Association (ANA) and its 53 constituent nurses' associations will take part in activities to recognize the numerous contributions nurses make to the health of citizens of the US.

"Nurses Together in Caring" is the theme adopted by ANA for this year's nursing celebration. Nurses play a pivotal role in enhancing and promoting health care and the well-being of patients and family members. The US is experiencing a nationwide nursing shortage at the present time. During the next decade, more than 600,000 additional nurses will be needed. ANA and the state nurses' associations are working together to combat this shortage and misperceptions about nursing as a career. ANA is calling for organized groups to work together to solve the nursing shortage problem, help improve nurses' salaries and working conditions, and provide a greater role for nurses in decision-making processes. For additional information, contact: ANA, 2420 Pershing Road, Kansas City, MO 64108.

National Nurses' Day • May 7, 1990

Persistence of Anti-HBs among Health Care Personnel Immunized with Hepatitis B Vaccine

MARY T. PASKO, PHARM D, AND THOMAS R. BEAM, JR., MD

Abstract: Health care personnel who received the hepatitis B vaccine (Heptavax-B^R, MSD) were followed for persistence of hepatitis B surface antibody (anti-HBs). Response occurred in 135/146 (92.5 percent) vaccinees. Loss of anti-HBs (<72 RIA units; 10 S/N) occurred in 35.9 percent during the 36-month surveillance. Stepwise discriminant analysis found age and magnitude of initial antibody level, but not weight-height index, to be predictive of antibody loss over the 36 months. Twenty-four of 27 employees (88.9 percent) who lost anti-HBs responded to a fourth vaccine dose. In contrast, three of eight initial non-responders (37.5 percent) developed antibody after a fourth vaccine dose. (*Am J Public Health* 1990; 80:590–593.)

Introduction

Hepatitis B virus (HBV) infection is a significant occupational risk to health care personnel.[1–3] Safety and immunogenicity of the hepatitis B vaccine have been demonstrated in immunocompetent health care personnel.[4] However, current evidence from studies of healthy vaccinees and male homosexuals suggests serum antibody will not be maintained indefinitely.[5–9] Whether loss of demonstrable antibody can be equated with loss of protection against disease is not known.

The objectives of the present study were to determine prevalence of baseline antibody to hepatitis B surface antigen (anti-HBs) in our population, to evaluate response rate, and to monitor persistence of anti-HBs serially over three years. Non-responders and those responders who lost antibody (transient responders) were also evaluated and compared to the persistent responder group.

Methods

Participants were health care personnel at the Veterans Administration Medical Center, Buffalo, New York. The study was approved by the Human Studies Subcommittee and each participant signed informed consent prior to enrollment.

The clinic nurse recorded height, weight, health problems and/or medications upon entry into the study. A baseline serum sample was obtained and three doses of Heptavax-B^R (MSD) (20 mcg) were administered intramuscularly according to current recommendations; second and third doses were given one and six months after the first.[10]

Serum samples were collected 7, 12, 24, and 36 months following the first vaccine dose for determination of anti-HBs. Non-responders and those employees with demonstrable loss of anti-HBs to levels less than or equal to 72 radioimmunoassay (RIA) units were given a fourth vaccine dose (20 mcg). Fourth doses were given to non-responders two to three months after the third dose. Transient responders received fourth doses at variable intervals with respect to the third dose but within two to three months of a serum sample demonstrating anti-HBs ≤ 72 RIA units. Serum anti-HBs was then determined one month later. All sera from non-responders were tested for the presence of hepatitis B surface antigen (HBsAg).

Participants were asked to report any known or suspected exposure to HBV. Exposures were investigated by study personnel to determine whether a true HBV exposure occurred.

Serum Studies

Serum anti-HBs was determined in duplicate by radioimmunoassay (AUSAB, Ausria II; Abbott Laboratories, North Chicago, IL). Anti-HBs levels were quantitated according to manufacturer's directions and reported as radioimmunoassay units (RIA units).[11] In our laboratory, 72 RIA units correlated with 10 S/N units (ratio of sample counts per minute to mean counts per minute in antibody negative controls).

Vaccine response was defined as an anti-HBs value of greater than 72 RIA units (10 S/N). Those with a maximal anti-HBs value of 72 or less either 7 or 12 months after the first vaccine dose were considered nonresponders. Persistent responders were those whose anti-HBs values exceeded 72 RIA units (10 S/N) throughout the period of study. Those responders whose anti-HBs values initially exceeded 72 RIA units but declined below this value during the course of the study were considered transient responders.

Weight-height index was calculated as weight (kg)/{height (m)}^{p}, where p equals 2 for males and 1.5 for females.[12]

Statistical Analysis

Data analysis was accomplished with the use of the Statistical Package for Social Sciences (SPSS-PC) (v.2.0; SPSS Inc., Chicago, IL; 1988). Students t-test for unpaired data and stepwise discriminant analysis were performed; 95% confidence intervals (CI) for mean differences were calculated.[13]

Results

Baseline Screen for Anti-HBs

Of 184 employees screened for the presence of serum anti-HBs, 14 (7.6 percent) were found to be positive (>8 RIA units; 2.1 S/N). Anti-HBs levels in six of the 14 sera (42.9 percent) were 72 RIA units or less while eight sera (57.1 percent) exceeded this value. Those with baseline anti-HBs > 8 RIA units were excluded from further analysis.

Response to Vaccination

Of the 170 employees with negative baseline serum, 17 employees either did not complete vaccination or were lost to

From the Infectious Diseases Section, Buffalo VA Medical Center, and the School of Pharmacy and Medicine, State University of New York at Buffalo. Address reprint requests to Mary T. Pasko, PharmD, Infectious Diseases Section (111F), VA Medical Center, 3495 Bailey Avenue, Buffalo, NY 14215. This paper, submitted to the Journal August 17, 1989, was revised and accepted for publication December 4, 1989.

© 1990 American Journal of Public Health 0090-0036/90$1.50

follow-up and seven employees received injections in the buttocks. All of these were excluded from further analysis.

Among the 146 employees remaining, 135 (92.5 percent) responded while 11 (7.5 percent) were non-responders. The mean age of the study population was 36.0 ± 9.9 years. Non-responders (mean 40.5 years) were slightly older than responders (mean 35.7 years; 95% CI of difference = 2.8, 12.4). The mean calculated weight-height index for responders (29.6 ± 6.3) and non-responders (28.9 ± 5.3) was similar.

Persistence of anti-HBs

Antibody concentrations declined to 72 RIA units (10 S/N) or less in 6 of 133 employees (4.5 percent) at 12 months, 21 of 115 (18.3 percent) at 24 months, and in 33 of 103 (32.0 percent) at 36 months after the first vaccine dose (Figure 1). The duration of anti-HBs was related to the magnitude of the antibody response measured seven months after the first vaccine dose (Table 1).

To further characterize the persistent and transient responders, 92 individuals were evaluated from whom serial anti-HBs values were available 7, 12, 24 and 36 months after the first vaccine dose. These 92 individuals were similar with respect to age, initial anti-HBs level and weight-height index when compared to the 43 responders for whom follow-up was incomplete. Anti-HBs levels were maintained above 72 RIA units (10 S/N) in 59 individuals (64.1 percent) for the 36-month period, while 33 (35.9 percent) were transient responders.

Stepwise discriminant analysis revealed that magnitude of the initial anti-HBs concentration and age were significant discriminators of antibody persistence or loss within the 36-month period. Transient responders were older than persistent responders and the magnitude of initial anti-HBs was substantially higher among persistent responders. The weight-height index (WT-HT) was not found to be of predictive value (Table 2).

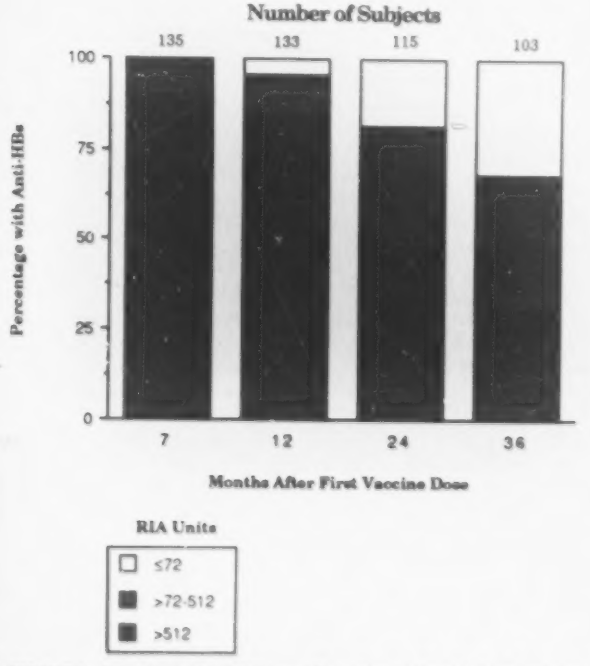

FIGURE 1—Persistence of Anti-HBs over Three Years in Health Care Personnel Who Responded to the Three-dose Vaccine Series

TABLE 1—Loss of Anti-HBs 36 Months after Vaccination (N = 103)

Initial Anti-HBs[a]		No. < 10 S/N	Duration of Anti-HBs (months)[b]

72–512	10–50	11/11 (100)	16.3 ± 6.2
>512–5000	50–1000	14/21 (66.7)	25.5 ± 7.1
>5000	>1000	8/71 (11.3)	32.6 ± 3.4

[a]measured 7 months after first vaccine dose.
[b]mean ± standard deviation of time (months) that anti-HBs ≥ 10 S/N.

Exposure to HBV

Twenty-five employees reported 110 exposures to potentially HBsAg positive blood or body fluid. Exposures involved direct contamination of mucous membranes or abraded skin with blood or other body fluids; none was an accidental needle stick. Antigen status of the patients was determined or known in 104 of the 110 (95 percent) incidents and 30 (29 percent) involved HBsAg positive patients. The 30 documented exposure events occurred among nine employees, two of whom were non-responders. None of the nine employees developed HBsAg.

Revaccination of Non-responders and Transient Responders

Response to a fourth vaccine dose was assessed in 27 transient responders and eight non-responders. In comparison to the response elicited following the initial three-dose series, anti-HBs following the fourth dose was of similar or greater magnitude in 24 of 27 (88.9 percent) transient responders. Anti-HBs exceeded initial magnitude by three-fold or greater in 13 individuals (48.2 percent), was of similar magnitude in 11 (40.7 percent), and declined in two individuals (7.4 percent). In one case (3.7 percent), the fourth dose failed to evoke any anti-HBs response. However, this individual initially demonstrated a low antibody response to the three-dose series (anti-HBs = 112 RIA units; 18 S/N). Persistence of anti-HBs following the fourth dose in this subpopulation is under continued evaluation.

In contrast, five of eight non-responders (62.5 percent) given a fourth dose failed to respond. Among the three individuals who responded, anti-HBs persisted above 72 RIA units (10 S/N) for 9, 27, and 36 months, respectively.

Discussion

The results of this study corroborate the findings of others but also provide important additional information about persistence of antibody levels and response to booster injections in recipients of plasma-derived hepatitis B vaccine (Heptavax-B). Since we found a low prevalence of hepatitis B markers among our employees (7.6 percent), these observations support the contention that antibody response and decline in our employee population was indicative of the vaccination process and not inadvertent exposures to contaminated blood and body fluids.

In the present study, initial response rate, magnitude of mean peak anti-HBs and loss of antibody within the first year were very similar to that reported by Dienstag, *et al*,[4] (Table 3), although the relation to age was not as strong as relation to initial response. Other studies[12,14,15] have found age to be an important factor distinguishing responders and nonresponders.

TABLE 2—Comparison of Persistent and Transient Responders followed Serially for 36 Months* (N = 92)

[c]Anti-HBs loss within 12–13 months of the first vaccine dose.

Although the influence of injection site on response rate is well established,[16] the role of obesity as a factor in response rate is less clear. In our study, no association was found between likelihood of response and weight-height index as a measure of obesity. In a previous study reporting an association,[12] all vaccine was administered in the buttocks with a 1-inch needle and thus the overall seroconversion rate was low as might be expected (55.7 percent). Horowitz, *et al*,[7] found an association between body mass index (weight/height^2) greater than 25 and prevalence of low antibody levels (<10 mIU/ml) at a median time of 39 months post-vaccination. The subpopulation with low anti-HBs (<10 mIU/ml) included non-responders as well as responders who lost antibody since vaccination. A recent case control study reported by the Centers for Disease Control (CDC) used an age-adjusted logistic model and found an association between obesity and nonresponse for females over the age of 19 years. A similar association was not found for males.[17]

Antibody persistence among vaccine responders in health care populations is of particular interest. During our 36-month surveillance, 32 percent of responders lost antibody (<10 S/N). Jilg, *et al*,[5] in a brief report of "healthy vaccinees" (inclusion groups not further characterized) found antibody in 27.5 percent of the study population fell to 10 IU/l (equivalent to 10 S/N) or below after four years. The authors do not comment on site of vaccine injection, age of their study population, or HBV exposure events.

Several additional studies have attempted to evaluate either initial response or antibody persistence following vaccination of health care personnel. However, vaccine was administered via gluteal injections in two reports[14,15] and response rate was low as expected. In an additional two reports,[9,10] initial antibody levels post vaccination (deltoid injections) were not obtained. Both authors assumed a response rate of 90–95 percent and thus the subset of employees reported to be negative for anti-HBs at the respective serum sampling times included non-responders and low level responders. Additionally, since baseline prevalence of anti-HBs is also unknown in these populations, those with persistent antibody as a result of natural infection cannot be distinguished from vaccine responders.

Extensive long-term follow-up of vaccinees has been reported by Hadler, *et al*, in a study of male homosexuals[6] and by Wainwright, *et al*, in an Eskimo population.[9] In the Hadler study, anti-HBs was maintained above 10 SRU (sample ratio units; equivalent to 10 S/N) in 93, 70, 65, 60, and 58 percent of the population at 12, 24, 36, 48, and 60 months of follow-up, respectively. Similar to Hadler's data, anti-HBs in our study was maintained above 72 RIA units (10 S/N or 10 SRU) in 95, 82, and 68 percent of vaccinees at 12, 24, and 36 months of follow-up. Preliminary review of our 48-month data indicates 52 percent of vaccinees are above 10 S/N (unpublished observation). This percentage is similar to that of Barnes, *et al*,[8] at 48 months (55 percent > 10 S/N). In contrast, Wainwright, *et al*,[9] report 73 percent above 10 S/N at five years post-vaccination for ages 20–49 and 63 percent for those over 50 years of age. Similar to our finding, initial antibody level was a stronger predictor of antibody persistence than age.

Characterization of responders who subsequently experience a loss of anti-HBs has not been previously reported. We found these transient responders to be somewhat older and have lower initial anti-HBs levels than those with persistent antibody. Evaluation of the response to booster doses and persistence of antibody is in progress. Preliminary results from a small group of our transient responders indicate that a single booster dose elicits a response equal to or greater in magnitude than the initial response in 89 percent of recipients. Continued follow-up of this group will provide further information about persistence of antibody.

While the majority of our transient responders developed anti-HBs after a fourth dose of vaccine, the need for booster doses of vaccine is controversial. Although progressive loss of anti-HBs occurs over time, immunity may outlast demonstrable antibody. Among male homosexuals in the Hadler study,[6] the risk of hepatitis B infection was greatest among vaccine non-responders or low level responders. Of the hepatitis B infections that occurred, 76 percent were in individuals whose anti-HBs was below 10 SRU (equivalent to 10 S/N). Only two cases of clinically important hepatitis developed among responders. Likewise, Wainwright, *et al*,[9] found only four cases of HBV infection over five years. All had anti-HBs level < 20 SRU (equivalent to 20 S/N), developed anti-HBc, remained negative for HbsAg, and were asymptomatic. Thus while current evidence suggests that maintenance of demonstrable antibody levels within five years of vaccination may be unnecessary for prevention of symptomatic disease, further studies are required to investigate the issue of life-long protection.

Maternal and Child Health Law Changes Explained

Recent legislative changes in the maternal and child health block grant program were spelled out in a letter sent by Dr. Robert G. Harmon, HRSA Administrator, to state health officers. The letter is intended to assist states in applying for fiscal 1991 maternal and child health block grant funds and in submitting the fiscal 1989 annual report on state activities funded under this program.

The law was amended by the Omnibus Budget Reconciliation Act of 1989 (Public Law 101-239). The amendments "create a new framework for action on maternal and child health for the 1990s," Dr. Harmon noted.

The amendments, which increase the authorization for appropriations to $686 million for fiscal 1990 and subsequent years, are designed to:

- Promote the PHS Health Objectives for the Nation for the Year 2000;
- Assure expenditure of funds for preventive and primary care services for children and for services for children with special health care needs;
- Improve data collection and analysis; and
- Increase overall accountability in the administration of the program.

The amendments also make structural changes in the block grant to improve state planning, accountability, and targeting of federal funds to priority populations. The changes:

- Prescribe new requirements for the use of allotment funds;
- Establish a new application requirement;
- Establish new state and federal reporting on services, expenditures and health status of target populations; and
- Mandate additional state and federal activities to promote improved access to maternal and child health services.

The changes reflect "work remaining to be done by federal and state authorities in developing effective statewide systems of comprehensive, community-based family-centered continuous care," Dr. Harmon wrote. "They encourage using resources better through effective coordination of MCH block grant activities with those of other major maternal and child health assistance programs providing related services to similar populations."

Carbon Monoxide in Indoor Ice Skating Rinks: Evaluation of Absorption by Adult Hockey Players

BENOÎT LÉVESQUE, MD, ERIC DEWAILLY, MD, MSc, ROBERT LAVOIE, MD, DENIS PRUD'HOMME, MD, MSc, AND SYLVAIN ALLAIRE, BSc

Abstract: We evaluated alveolar carbon monoxide (CO) levels of 122 male, adult hockey players active in recreational leagues of the Quebec City region (Canada), before and after 10 weekly 90-minute games in 10 different rinks. We also determined exposure by quantifying the average CO level in the rink during the games. Other variables documented included age, pulmonary function, aerobic capacity, and smoking status. Environmental concentrations varied from 1.6 to 131.5 parts per million (ppm). We examined the absorption/exposure relationship using a simple linear regression model. In low CO exposure levels, physical exercise lowered the alveolar CO concentration. However, we noted that for each 10 ppm of CO in the ambient air, the players had adsorbed enough CO to raise their carboxyhemoglogin (COHb) levels by 1 percent. This relationship was true both for smokers and non-smokers. We suggest that an average environmental concentration of 20 ppm of CO for the duration of a hockey game (90 minutes) should be the reference limit not to be exceeded in indoor skating rinks. (*Am J Public Health* 1990; 80:594–598.)

Introduction

Over the past few years numerous cases of carbon monoxide (CO) intoxication in indoor skating rinks have been described in medical literature.[1–9] Most often, the victims have been hockey players, and the source of the contamination has been the ice resurfacing machine.

When inhaled, CO quickly enters the bloodstream where once having displaced the oxygen, it becomes associated with hemoglobin to form carboxyhemoglobin (COHb). The percentage of COHb is the main indicator of the absorption of this toxic gas. It is generally equal to 1 percent among non-smokers[10] and may reach 5 to 10 percent among smokers.[11]

Following acute exposure to CO, there is a rapid increase in the COHb level. At the 3 to 4 percent level, the first signs of adaptation in healthy individuals take the form of an alteration of alertness[11] and arterial dilation in response to a drop in blood oxygenation.[12] These levels are sufficient to worsen coronary symptoms among persons with cardiac problems.[13–16] At 4 percent, careful driving skills are affected,[17] and, between 5 and 10 percent, visual acuity is decreased.[12] Levels between 10 and 20 percent cause headaches and difficult breathing.[12] At 20 percent, headaches worsen, nausea appears and manual dexterity is affected.[12] At 40 to 50 percent, all symptoms intensify, and between 50 and 60 percent, there is a possibility of coma.[12]

Gasoline or propane-driven ice resurfacers give off combustion by-products in their exhaust fumes. Depending on how well the unit operates, there will be a variable level of CO emitted. The problem is generally aggravated by poor ventilation in indoor rinks. The combination of these two factors often results in high levels. The CO reaches its maximum concentration when the ice resurfacer is in operation and gradually drops afterwards.[18]

Extremely high levels of CO have been documented in skating rinks with some levels exceeding 100 parts per million (ppm).[1,3,6,8,9,18–21]

CO absorption is up to three to four times higher during exercise than during rest.[22] We conducted a study among male adult hockey players of the Quebec City area to evaluate the CO absorbed by the players at the end of a 90-minute game. The data were collected between October 26, 1988 and January 28, 1989.

Methods

We chose 10 of the 16 voluntary hockey teams, each playing in its own indoor rinks, guiding our choice on various indicators such as the age and size of the rink, the type of resurfacing machine, and whether or not there was a mechanical ventilation.

Measuring Absorption

To measure absorption, subjects, standing up, took a deep breath which they held for 20 seconds. They then exhaled first into one polyvinyl chloride 900 mL bag and then into two other bags joined by plastic tubing (Tygon). The second sample filled with alveolar air was analyzed within 12 hours using a Bendix 8501-BA infra-red CO analyzer. The quantification technique was developed beforehand, and the correlation between the CO concentration in the alveolar air in ppm and the percentage of COHb was established using a sample of 24 volunteers (13 smokers and 11 non-smokers).[23] The square of the linear correlation coefficient (r^2) was .99, the intercept was −.003 ppm with a standard error of .005 ppm, the slope was 5.39 ppm (5.4 ppm of alv CO ≈ 1% COHb) and the standard error of the slope was .13 ppm.

For each player, the alveolar CO was measured within 15 minutes before and after the game. The difference between the two results represented the CO absorbed by the subject during the match in ppm (ΔalvCO).

Measuring Exposure

Exposure was measured by collecting seven samples of air at 15 minutes intervals, from the players' arrival on the ice rink to their departure. The samples were taken from the penalty box located 1.2 meters above the ice using a Gilian HFS-113A pump and Calibrated Instrument 5 L aluminized bags. Pump flow was set at one liter per minute. These samples were analyzed within 12 hours on the Bendix spectrometer. The average of the seven samples was con-

sidered the level of exposure by players during the game ([CO]).

Other Variables

Player's age and whether a smoker or non-smoker were obtained by questionnaire. The pulmonary function was quantified with a Roxon Compact vitalograph using the standardization criteria of the American Thoracic Society.[24] We determined the forced expiratory volume in one second (FEV_1), the forced vital capacity (FVC), the mean forced expiratory flow (FEF_{25-75}) and the FVC/FEV_1 ratio. The expected values were estimated using the Knudson method.[25] Finally, players' aerobic capacity ($\dot{V}O_2max$) was evaluated using a sub-maximum progressive effort test on an ergometric bicycle. The initial work load was set on the basis of the weight of the individual and increased progressively by 240 kiloponds meter (Kpm) for four two-minute levels. The $\dot{V}O_2max$ was estimated based on the equation suggested by the American College of Sports Medicine (26).

Statistical Analysis

The data were stratified according to smoking habits (smokers vs non-smokers). In addition to CO exposure, we examined the influence of age, $\dot{V}O_2max$ and the various spirometric indices on absorption, in a multiple regression model using a backward elimination procedure.[27] The pre-selected critical value of the F distribution was set for a significance level of .05. The resulting relationship between absorption and exposure was evaluated with a simple linear least squares regression model using individual values. When heteroscedastic, it was weighted by the inverse of the variance of the means to confirm the validity of the statistical tests.[27] To verify the possible parallelism between smokers and non-smokers, the coefficients were compared with the addition of a term of interaction.

Results

We evaluated 122 players in 10 teams, 32 smokers and 90 non-smokers. Their age varied between 19 and 59 years old (mean = 34.04 years, standard deviation = 7.10 years).

The various spirometric parameters (FEV_1, FVC, FEF_{25-75}, FVC/FEV_1) as well as the age and the $\dot{V}O_2max$ were eliminated by the backward elimination procedure (data available on request to authors). It seems that these variables have very little effect on CO absorption, whatever the smoking habits. As a result, these variables were not considered factors likely to alter the exposure/absorption relationship.

Tables 1 and 2 describe by indoor rink, for non-smokers and smokers respectively, exposure concentrations in ppm, the number of players, the average quantity of alveolar CO (mean and variance) absorbed during the game and the estimated equivalent in percentage of COHb (5.4 ppm alv CO ≈ 1% COHb).

The exposure levels varied from 1.6 to 131.5 ppm. Seven rinks were below 20 ppm, whereas three exceeded 75 ppm.

Table 1 shows that with low exposures (rinks 1 and 3), non-smokers had, at the end of their game, lowered their COHb concentration. In seven other rinks there was absorption and it was proportional to the level of exposure. The concentration of 4 ppm noted in rink 4 represented a balance threshold where there was neither absorption nor elimination.

Table 2 shows an average drop in COHb among smokers at exposure levels as high as 15.1 and 16.2 ppm. This phenomenon is attributable to high basic levels among smokers.

TABLE 2—Variation in the Alveolar Absorption of Carbon Monoxide among Players during a 90-minute Hockey Game (ΔalvCO) and the Estimated Equivalent in Percentage of Carboxyhemoglobin (COHb) Based on the Concentration of Carbon Monoxide ([CO]) in the Indoor Skating Rinks among Smokers

Arena	Players N	[CO] (ppm)	ΔalvCO Mean Variance (ppm)	(ppm²)	COHb %
1	3	1.6	−6.38	46.32	−1.20
2	2	9.3	−27.72	20.58	−5.23
3	3	1.6	−10.68	11.30	−2.00
4	1	4.0	−18.13	—	−3.42
5	1	9.5	−13.79	—	−2.60
6	4	15.1	−2.38	31.42	−0.45
7	6	131.5	51.50	299.45	9.72
8	6	107.3	45.66	98.87	8.61
9	4	16.2	−9.93	1.81	−1.87
10	4	79.3	34.80	357.27	6.57

Figures 1 and 2 show the relationship between exposure and absorption using a simple linear regression model.

Figures 1 illustrates this model among non-smokers. The r^2 was equal to 0.97 and the intercept to −1.72 ppm (standard error = .69 ppm). This small negative intercept reflected the CO elimination in low exposure concentrations for the non-smokers. The slope at 0.55 ppm (standard error = .01 ppm) indicated that for every 10 ppm of exposure, an adult hockey player (non-smoker) had, at the end of a 90-minute game, absorbed enough CO to raise his alveolar CO concentration by 5.5 ppm (≈1% of COHb). The F ratio was 2681.36 for a significance level below 0.0001. The test had to be interpreted with caution given the heteroscedasticity of the data. Indeed, there was an increase in the variability of absorption proportional to the level of exposure (see Figure 1 and Table 1). For exposures of 1.6 and 131.5 ppm, absorption varied respectively from −0.9 ppm to 0.1 ppm (range = 1 ppm, variance = 0.10 ppm²) and from 51.1 ppm to 87.4 ppm (range = 36.3 ppm, variance = 128.90 ppm²). To correct this situation, the results were weighted with the inverse of the variance of the means. The results of the regression and the test continued to be very significant ($F = 1454.70$, $p < 0.0001$).

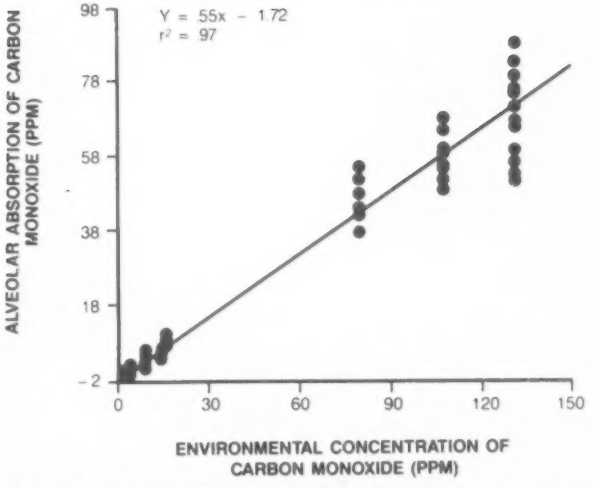

FIGURE 1—Relationship between Alveolar Absorption of Carbon Monoxide among Players during a 90-Minute Hockey Game based on Carbon Monoxide Concentrations in Indoor Skating Rinks (non-smokers).

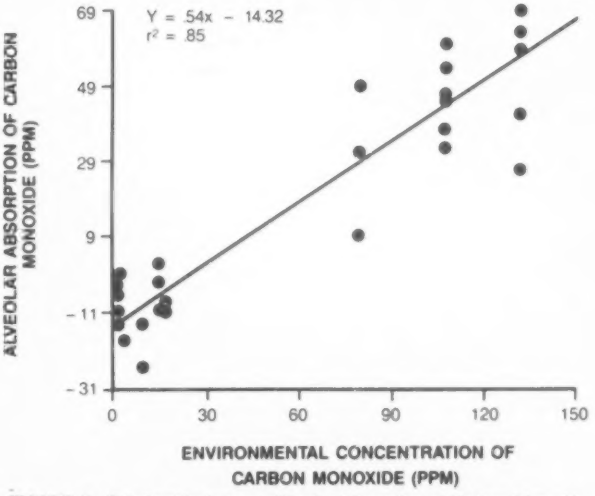

FIGURE 2—Relationship between Alveolar Absorption of Carbon Monoxide among Players during a 90-Minute Hockey Game Based on Carbon Monoxide Concentrations in Indoor Skating Rinks (smokers).

Among smokers (Figure 2), the r^2 was equal to 0.85 and the intercept to −14.32 ppm (standard error = 3.1 ppm) indicated the effect of exercise on CO elimination with elevated basic levels of alveolar CO. The F ratio was 169.50 ($p < 0.0001$). The slope at 0.54 ppm (standard error = .04 ppm) was not considered statistically different to that of non-smokers ($p = .6607$). As a result, after a 90-minute game of hockey, smokers and non-smokers alike increased their concentration of COHb by 1 percent for every 10 ppm of exposure to CO in the indoor rink.

Discussion

There are two types of standards for CO: standards for workers and standards for the public in general.

In an occupational environment the National Institute for Occupational Safety and Health (NIOSH) recommends a maximum time-weighted average (TWA) of 35 ppm for an eight-hour work day and a ceiling concentration of 200 ppm.[10] In the province of Quebec (Canada), the prevailing regulation stipulates 50 and 400 ppm for the same parameters.[28]

These values cannot apply to a hockey player playing in a recreational league. The latter, besides practicing his sport during his leisure time, is involved in an activity that required an energy expenditure greater than the workers. For example, the average energy expenditure of professional activities like lumberjack, mason, miner or carpenter is between 5.0 and 6.4 Mets (1 Met = 3.5 mL $O_2 \times Kg^{-1} \times min.^{-1}$).[29] For a hockey player, it is 12.9 Mets (min. = 9, max. = 15), a greater quantity than a soccer player (10.3 Mets, min. = 8, max. = 12) or a basketball player (11.1 Mets, min. = 9, max. = 13).[29] It is therefore necessary to look to criteria that apply to the general public.

Table 3 gives a summary of Canadian[30] and American[31] standards and of the recommendations of the World Health Organization (WHO).[32] These levels have been deduced using empirical equations based on the controlled exposure of volunteers. Apart from the desirable Canadian standard, they aim at maintaining the COHb concentration for non-smokers at 2 percent, thus protecting the most vulnerable segment of the population from the harmful effects of CO. The desirable Canadian standard aims at allowing an average COHb content below 1 percent, namely the equivalent of the endogenic production of a non-smoker.[30]

In indoor rinks, the British Columbia Department of Labor (Canada) has proposed a reference limit of 25 ppm[8] and, following a review of the literature on the subject, Luckurst and French suggested CO concentrations of 25 and 12 ppm for one hour and eight hours, respectively.[33]

The study that we conducted allowed us to ascertain extremely high CO concentrations in three indoor rinks out of 10. These levels even exceeded the standards set for workers.

Beyond environmental measurements, the best way to describe the risk involves using biological measurements. Only one author has shown interest in this aspect. Spengler evaluated alveolar breath samples among 12 Harvard University players before and after 90 minutes of exercise. An average concentration of 22.5 ppm of CO in the air was sufficient to raise the average COHb level by 1.1 to 3.2 percent.[18]

We succeeded in determining the absorption curve of adult hockey players who practice their sport on a recreational basis, and we noted that absorption was directly related to exposure.

There was great individual variability of absorption at the same CO exposure. For the non-smokers, at low level of CO, the intrateam variability was very low (variance = .316 ppm^2 for teams 1 and 3). At higher exposures, the observed

variability may be explained in part by the analytical error on the measure of alveolar CO itself.[23] Also, other variables undocumented here can probably affect the individual CO absorption at these levels. The ratio of the tidal air to the dead space of the lung and the diffusion constant of the lung can explain some divergencies in the CO uptake.[22] Moreover, factors which affect the players' activity may be important. For example, Green showed differences in the time-motion characteristics (actual playing time, number of playing shifts, recovery time between shifts, etc.) between players depending on the position played (center, wing, defense).[34] In addition for the smokers, the variability of the pre-exposure alveolar CO level is certainly an important factor.

In the more exposed teams (#10-8-7), the average increase of COHb were respectively 8.70 percent, 10.82 percent, and 13.17 percent. Some players had an increase up to 17 percent. Levels like this are certainly sufficient to cause headache, breathing difficulties and, for some people, nausea.[12] They can also alter the choice reaction time,[11] the driving skills,[17] and the visual acuity.[12] All these toxic actions can contribute to accidents on the skating rinks and on the road at the end of the game.

At the present time there are no reliable data on cardiac pathology among hockey players. However, sudden increases in COHb as noted here may have a significant impact on the triggering of an irreversible ischemia. Particularly, if they are within the framework of intense physical exercise. Montgomery estimated for 12 adult recreational players that the intensity of hockey play assessed by the Karvonen method was 85 percent.[35] This represents a strenuous activity and, by itself, it can strain the cardiovascular system.[35] All these considerations make CO a significant threat for the population under study.

Generally, these players drop out of hockey several years and then return to improve their physical fitness or for the friendship obtained.[35] They are often ill-prepared for such intense physical exercise and, of all the groups frequenting indoor rinks, they are probably the most susceptible to the harmful effects of CO given the high level of absorption conferred by the intensity of their activity. If a standard is to be issued, we believe that they should serve as a reference.

We find absurd the idea that a hockey player must adapt to a toxic gas. A 3 percent COHb threshold, which is sufficient to induce physiological compensation mechanisms, must be the reference index. Considering that non-smokers have COHb levels of 1 percent and less, an increase of more than 2 percent cannot be accepted during the hockey game. This corresponds, for the duration of the hockey game (90 minutes), to an average concentration of 20 ppm in the air of the indoor rink, and as a result, it is the limit we propose.

If we rely on the data of our study, this norm is realistic since seven indoor rinks in 10 fell within it. When an ice resurfacing machine with a non-polluting motor (electrical, hydrogen) is not available, there are three means of respecting this norm: good maintenance of the ice resurfacing machine, sufficient mechanical ventilation used wisely, and routine monitoring of CO levels in indoor skating rinks.[7,8,20,36]

ACKNOWLEDGMENTS

This study was made possible through a grant from the Régie de la Sécurité dans les Sports du Québec as part of a concerted action with the Fonds pour la Formation de Chercheurs et l'Aide à la Recherche (FCAR). We would like to thank these two organizations for their cooperation. We would also like to mention the contribution of the Association des Arénas du Québec, the Direction de l'assainissement de l'air of the ministère de l'Environnement du Québec, the Pneumology Department (Hôpital Laval), as well as Sonia Tennina and Jeannette Mercier for their statistical consultation work and technical support in inhalation therapy respectively.

AADS to Offer Oral Health Education for Elderly

The American Association of Dental Schools (AADS) is preparing an education packet to help older persons take better care of their oral health. Funding for the program is being provided by a $49,479 grant from the W. K. Kellogg Foundation.

Through the AADS project, copies of the oral health education packets will be distributed to 55 dental schools and 200 dental hygiene education programs nationwide. Beginning in the Fall 1990, the dental and dental hygiene students will give one-hour presentations at senior centers, clubs, churches, and volunteer organizations, with a special emphasis placed on reaching minority older persons.

The educational materials will be prepared by a team of dentists, dental hygienists, a social worker, and dental educators. By conducting the training, the students will gain first hand experience about oral health and its relation to the aging process, as well as learn to communicate effectively with elderly persons and to network with other health professionals.

For more information, contact the American Association of Dental Schools, 1625 Massachusetts Avenue, Suite 502, Washington, DC 20036; (202) 667-9433.

Passive Smoking and 20-Year Cardiovascular Disease Mortality among Nonsmoking Wives, Evans County, Georgia

CHARLES HUMBLE, MS, JANET CROFT, MPH, ANN GERBER, MSPH, MICHELE CASPER, MSPH, CURTIS G. HAMES, MD, AND HERMAN A. TYROLER, MD

Abstract: The association of passive smoking and cardiovascular disease (CVD) mortality was assessed in a cohort of 513 rural, married Black and White women who were disease-free and self-described as never-smokers at baseline in 1960. Over a 20-year period, 76 of 147 total deaths were attributed to CVD. Relative risk estimates adjusted for age, cholesterol, blood pressure, and body mass from proportional hazards models were 1.59 for CVD (95% CI = 0.99, 2.57) and 1.39 (CI = 0.99, 1.94) for all cause mortality among women with husbands who smoked cigarettes. (*Am J Public Health* 1990; 80:599–601.)

Introduction

Cardiovascular diseases account for about one-half of all deaths in the United States annually.[1] Although active smoking is well-established as a CVD risk factor,[2] the risk for all CVD mortality associated with passive smoking among nonsmokers has not been previously investigated. Recent studies of risks for coronary heart disease,[3–8] stroke,[4,5] or all cause mortality[7,9,10] associated with passive smoking generally have reported weak and/or statistically nonsignificant results.

The 20-year mortality experience of nonsmoking women in Evans County, Georgia was used to assess the association of passive smoking with CVD and all cause mortality. This is the first report that includes data on both Blacks and Whites and on the consistency of self-reported smoking behaviors over time.

Methods

In 1960–61, 92 percent of all residents ages 40–74 years and a 50 percent sample of individuals ages 15–39 years in Evans County, Georgia participated in a cardiovascular disease study that included risk factor measurements, complete physical examinations, and a demographic and medical history interview.[11] Detailed descriptions of the Evans County study design and the 20-year mortality follow-up of the cohort have been reported elsewhere.[11–13] At baseline, 554 (82 percent) White and 389 (83 percent) Black women, among a total of the 1,127 women ages 40–74, reported that they had never smoked. The present study was restricted to the 328 White women and 185 Black older women who had never smoked and were married to male examinees who reported they either had never smoked or were current smokers at baseline. Women married to ex-smokers were excluded from the analyses as the probability for misclassification of these subjects' own smoking habits and those of their husbands was judged to be higher than for spouses of never smokers.[14] A second survey of study subjects in 1967 provides data on the stability of reported smoking status.

Vital status was determined as of May 1, 1980. Underlying cause of death was abstracted from death certificates with codes 390-456 (ICD 8th Revision) defining CVD. All CVD mortality was chosen as an endpoint given the limitations of death certificate data and the small number of deaths attributed to each specific CVD entity.[13] Three subjects who did not have follow-up information were excluded.

Analyses for White women were stratified by social status because of its inverse relationship with smoking status and CVD mortality in this cohort.[13] White women were divided into high social status and low social status groups based on the median of the McGuire-White index of social status for all Evans County Whites. This index, based on occupation, level of education, and source of income of the head of household, was developed for use in rural settings.[15] Since only 5 percent of the Black women in the Evans County population had a social status score above the median for Whites, Blacks were not stratified by social status. Exposure to passive smoking was defined by husband's smoking status (current, never) at the time of the baseline interview.

Mean baseline characteristics by passive smoke exposure were compared using t-tests. Cox proportional hazards models[16] were used to estimate the association of passive smoking with time to all CVD, smoking-related CVD, and all cause mortality in this population while adjusting for age alone and for age, systolic blood pressure, serum cholesterol, body mass index (BMI), and a quadratic term for BMI. Relative risks (RR) and 95% confidence intervals (CI) were calculated using the SAS proportional hazards (PHGLM) modeling procedures,[17,18] and the statistical significance of trends was tested using a method proposed by Rothman.[19] Constancy of the relative risks over time was verified before the proportional hazards were modeled.

Results

Among nonsmoking married women, there were 179 (55 percent) of 328 White women and 117 (63 percent) of 185 Black women whose husbands reported current cigarette

TABLE 1—Mean and Standard Error of Baseline Characteristics by Passive Smoking Status of Nonsmoking Wives, Ages 40–74 Years, Evans County, Georgia, 1960–61

	White Women				Black Women	
	High Social Status*		Low Social Status*			
	Exposed	Unexposed	Exposed	Unexposed	Exposed	Unexposed
N	(78)	(83)	(101)	(66)	(117)	(68)
Age	51.9 ± 1.0	54.9 ± 0.9	52.1 ± 0.8	53.9 ± 0.9	50.3 ± 0.7	55.5 ± 1.0
Systolic Pressure	145.5 ± 3.1	150.6 ± 2.9	151.6 ± 2.9	157.6 ± 4.3	170.6 ± 3.4	176.5 ± 5.0
Diastolic Pressure	88.4 ± 1.6	90.6 ± 1.4	92.2 ± 1.3	93.1 ± 1.7	103.1 ± 1.9	103.9 ± 2.5
Serum Cholesterol	231.9 ± 4.9	237.5 ± 4.5	227.0 ± 4.4	235.7 ± 7.3	216.5 ± 3.9	216.2 ± 4.6
Body Mass Index	26.3 ± 0.6	26.4 ± 0.6	27.0 ± 0.5	28.6 ± 0.9	29.2 ± 0.6	30.0 ± 0.9

*Based on the median of McGuire-White scores for all White subjects.

smoking behavior. Among both Black and White women there were no statistically significant ($p < 0.05$) differences by passive smoking status for systolic or diastolic blood pressure, serum cholesterol or body mass (Table 1). However, passively exposed Black women and high social status White women were younger on average than nonexposed wives by 5.2 years (95% CI = 3.0, 7.6) and 3.0 years (95% CI = 0.3, 5.5), respectively. For all Whites combined, nonexposed women were also more likely to be above the median SES (socioeconomic status) level than passively exposed women (55.7 percent vs 43.6 percent).

Comparison of self-reported smoking status in 1960 and 1967 showed 98 percent of wives again reported themselves as never having smoked in 1967. Similarly, 98 percent of never smoking husbands maintained their reported status in 1967 while 25 percent of husbands who smoked in 1960 described themselves as non-smokers in 1967.

Age-adjusted RRs for all CVD, smoking-related CVD, and all cause mortality among passively exposed wives were elevated in Blacks and high social status Whites and for all subjects combined (Table 2). The opposite relationship of mortality with passive smoking status was found for low social status White women. Adjustment for other established CVD risk factors (blood pressure, cholesterol, and BMI) generally caused modest elevations of the risk estimates (Table 3) but as with the age-adjusted estimates, the confidence intervals for all subject groups included unity. A trend in risk over level of husband's smoking as reported in 1960 was only seen among high social status Whites; RRs for both total and smoking-related CVD mortality among wives whose husbands smoked <10, 10–20, and >20 cigarettes per day as compared to wives of nonsmokers were 1.02, 2.11, and 2.55, respectively (p for trend <0.06). A marginally significant ($p < 0.09$) trend in risk for all CVD and smoking-related CVD over crude levels of duration of exposure was also apparent only among high social status White women.

Discussion

These data suggest an elevation of risk for death from CVD and all causes among non-smoking married women whose husbands described themselves as current smokers at the beginning of a 20-year follow-up period. Our findings for Blacks are the first report associating CVD with passive smoking in this racial group. Our observations that social status may modify the effect of passive smoke exposure may be due to chance, but a similar pattern of results for coronary heart disease (CHD) has been reported in other studies of passive smoking. Nonsignificant ($p > 0.05$) two-fold RRs for CHD among passive smokers were reported from studies of middle-class and upper-middle-class women[6] and men[7] while CHD risk was significantly but more modestly increased (RR = 1.2) among a much larger sample of predominantly blue collar Washington County, Maryland women.[8] No increased risk for CHD was reported among public hospital patients whose husbands smoked in four British hospital regions.[5]

It is unlikely that these results can be explained by a change in smoking habits since the minimum age of these women in 1960 was 40. We lack data to examine whether exposure status changed during follow-up due to remarriage. The absence of elevated risk among exposed low social status

White women may reflect a failure of our passive exposure index to measure exposure within the lower social stratum. Power to test for small differences in effect of passive smoking by race or social standing was lacking as were data to evaluate the role of other variables such as alcohol use or physical activity. Taken together with the results of previous studies[6–8,10] and laboratory results suggesting that passive smoke exposure causes decreases in energy production in the mitochondria of heart muscle[20] and increased platelet aggregability in nonsmokers,[21] our results support the health hazards of exposure to passive smoke.[20]

Community Impact of a Localized Smoking Cessation Contest

HARRY A. LANDO, PHD, BARBARA LOKEN, PHD, BETH HOWARD-PITNEY, PHD, AND TERRY PECHACEK, PHD

Abstract: The present study assessed the effectiveness of a localized community contest timed to coincide with a statewide smoking cessation contest. Follow-up interviews were conducted with 218 local contest participants and 198 participants from the statewide contest. Overall cessation impact (participation rate × abstinence) was 0.39 percent for the local contest and 0.09 percent for the statewide contest. Localized community contests offered in conjunction with statewide or national campaigns may represent cost-effective methods of reaching large numbers of smokers. (*Am J Public Health* 1990;80:601–603.)

Introduction

Contests to promote smoking cessation appear to represent cost-effective means of producing quit attempts in community settings.[1–3] Quit smoking contests have been offered on a number of occasions as part of the smoking intervention in the Minnesota Heart Health Program (MHHP), a 10-year research and demonstration project intended to reduce the prevalence of heart disease.[4,5]

Several smoking cessation contests have been timed to coincide with the Great American Smokeout conducted annually by the American Cancer Society (referred to as "D-Day" in Minnesota). The present study examined contest participation and outcome for samples of Twin Cities area residents in the 1984 Minnesota D-Day contest. Participants from one of the intervention communities (Bloomington) were compared with a random sample of those from other Minneapolis suburbs (not within the immediate Bloomington area). It was hypothesized that the overall impact of a contest, measured by participation and abstinence outcome, offered in conjunction with specific localized community recruitment and prizes would be greater than that of the statewide contest alone.

Method

Subjects were recruited for a statewide D-Day contest during the Fall of 1984. Recruitment began August 25, 1984

optimistic to assume that similar results can be achieved elsewhere simply by adding a local promotion to a statewide contest.

Smoking and Consistently High Use of Medical Care among Older HMO Members

DONALD K. FREEBORN, PHD, JOHN P. MULLOOLY, PHD, CLYDE R. POPE, PHD, AND BENTSON H. MCFARLAND, MD, PHD

Abstract: Smoking behavior of consistently high and low users of medical care services were compared in two groups of older health maintenance organization (HMO) members continuously enrolled for five years and a subgroup who were continuously enrolled for 10 years. Smokers and former smokers, combined, were more likely than never-smokers to be consistently high users of ambulatory services (52 percent vs 34 percent in the five-year group, and 45 percent vs 30 percent in the 10-year group). (*Am J Public Health* 1990; 80:603–605.)

Introduction

Although the increased risk of morbidity and mortality associated with cigarette smoking is well established, the effect of smoking on the use of health services is less clear.[1–3] A number of studies have examined utilization patterns among the elderly,[4–7] but few have examined the relation between smoking and utilization. To our knowledge, no research has examined the relation between smoking and long-term ambulatory utilization patterns among persons 65 years of age and older.

This study seeks to determine: whether smoking behavior is an independent predictor of consistently high use of ambulatory medical services over periods of five and 10 years; and whether, when individuals are categorized as consistently high or low users of services, smokers (defined as current and former smokers) *within* the consistently high or consistently low user group use more medical services and resources than non-smokers (defined as persons who have never been smokers).

Methods

Data Sources

Study subjects were members of Kaiser Permanente (KP), Northwest Region, a large prepaid group practice HMO (health maintenance organization). Since January 1, 1967, medical record information has been routinely recorded for all medical contacts of a 5 percent sample of KP members.[8]

In 1970–71 the Center for Health Research at Kaiser Permanente conducted an extensive household interview survey of those subscriber units (families) in the 5 percent sample who were continuously enrolled in KP for the full two years of 1969 and 1970. The household survey was designed to obtain detailed individual and family demographic, social, economic, situational, behavioral, and attitudinal data, as well as health status data. The response rate was over 92 percent.[9] The survey and the outpatient utilization system for sample members age 65 and over (as of 1970–71) provide the data for this study.

Study Groups

Two study groups have been identified for this analysis:

- 312 sample members who were 65 years of age or older at the time of the survey, continuously enrolled in KP for the five-year period 1970–74, and alive at the end of 1975.
- A sub-group consisting of 203 sample members still alive at the end of 1980 who had been continuously enrolled for the 10-year period 1970–79.

Utilization Patterns

We determined the actual distribution of total ambulatory care contacts for each of the years 1970–74 for the first study group, and for the years 1970–79 for the second study group. Subjects were categorized as low, medium, or high users of services in each of the years according to the tertile into which their utilization fell.

TABLE 1—Background Characteristics by Medical Care Service Utilization Pattern

Characteristics	Consistently Low Users	Consistently Mixed Users	Consistenily High Users
Mean Age at Survey			
5-year group	70.7	71.5	71.2
10-year group	70.3	70.5	70.9
Percent Male			
5-year group	34.4	43.9	30.8
10-year group	27.7	34.1	18.2
Percent Married			
5-year group	54.7	63.3	65.4
10-year group	48.9	64.2	60.6
Percent High School Education or greater			
5-year group	29.7	38.1	42.3
10-year group	36.2	42.6	45.5
Income-Percent Less than $10,000			
5-year group	61.3	55.9	58.3
10-year group	65.2	55.1	60.7

TABLE 2—Smoking by Medical Care Service Utilization Pattern

	Consistently Low Users		Mixed Users		Consistently High Users		All Members	
	No.	%	No.	%	No.	%	No.	%
Group 1:1970–74								
Never smoked ($\bar{S}$)	42	65.6	127	66.1	25	48.1	194	62.9
Smoker, former smoker (S)	22	34.4	65	33.9	27	51.9	114	37.1
Total	64	100.0	192	100.0	52	100.0	308	100.0

90% Confidence Interval				−2.3–33.7				

Chi-squared test (Group 1) p = 0.05
Chi-squared test (Group 2) p = 0.19

For the first study group, those who were classified as high users in four or five of the years were defined as "consistently high users" (n = 52). Conversely, those classified as low users in four or five of the years were defined as "consistently low users" (n = 64). All others were defined as "mixed users" (n = 196).

For the second study group, those who were classified as high users in seven or more of the years were defined as "consistently high users" (n = 33). Those classified as low users in seven or more of the years were defined as "consistently low users" (n = 47). All others were defined as "mixed users" (n = 123).

Predictor and Control Variables

Both the predictor variable (smoking behavior) and the control variables (age, sex, marital status, and socioeconomic status) derive from the survey. Current and former smokers are combined in this study (and referred to as "smokers") because of the small number of cases.

In the five-year study group, 114 persons were included in the combined category of current and former smokers. Of this group, 67 percent were former smokers and 33 percent were current smokers. In the 10-year study group, the combined category included 35 persons (69 percent were former smokers and 31 percent were current smokers).

Analysis

To deal with potential confounding effects, we first examined the relation between the sociodemographic factors and the utilization patterns. None of the sociodemographic factors, individually or in combination, was associated with the utilization patterns (Table 1). The numbers, however, are small.

The analysis presented here is limited to the bivariate relationships between smoking behavior and patterns of use and, within categories of users, smoking behavior and resource use. The latter is defined as the number of office visits

+Costs are in terms of 1977 dollars

and hospital admissions per person per year, and the average per-person annual cost of ambulatory services.

Results

As shown in Table 2, for the five-year analysis, 52 percent of the high users compared to 34 percent of the low users were smokers (for the 10-year analysis, 46 percent vs 30 percent, respectively).

Table 3 shows that for both the five-year and the 10-year group, smokers had a higher rate of office visits and hospital admissions and greater average annual ambulatory costs per person than non-smokers. This pattern, however, does not obtain within the mixed user category.

Discussion

Elderly persons who were consistently high users of medical care were more likely than consistently low users to be smokers or former smokers; overall, smokers used more ambulatory care services than nonsmokers.

Limiting the study to long-term elderly HMO members may have understated the effects of smoking on the use of ambulatory medical services because of the differential survival rates of smokers and non-smokers. More smokers than nonsmokers may have been excluded from the study because of deaths. Nevertheless, the finding that, overall, non-smokers used less ambulatory services than smokers is consistent with the public health position that reductions in smoking will improve health status and reduce utilization.

Smoking cessation interventions can be successfully integrated into primary care practice and these interventions can be effective.[10] Long-term follow-up is needed to determine whether smoking cessation programs reduce subsequent utilization and the overall cost of medical care services.

Routine Communication in Sexually Transmitted Disease Clinics: An Observational Study

DEBRA L. ROTER, DRPH, NANCY KNOWLES, BA, MARK SOMERFIELD, MS, AND JULIE BALDWIN, BA

Abstract: Sixty STD patients were followed during the course of their clinic visit which averaged 2.75 professional contacts. Based on audiotape analysis, virtually all patients received a diagnosis; however, 25 percent of the patients did not receive any information about treatment or prevention, and only 57 percent of patients were given complete information. Patient recall of the information they were given averaged about 43 percent. Patients not seen by a physician during their clinic visit achieved higher recall rates than patients seen by a physician. (*Am J Public Health* 1990; 80:605–606.)

Introduction

Increasingly high rates of sexually transmitted diseases (STD) underscore the importance of Federal Quality Assurance Guidelines for STD Clinics.[1] According to guidelines, patient education should be routinely included in every patient visit and reinforced by every provider the patient sees. Validation of adherence to the Federal guidelines in STD clinics, however, has been infrequent.[2]

The current study was undertaken to observe directly provider-patient communication during routine STD clinic visits, to determine the extent to which diagnostic, treatment, and preventive information is given to patients as suggested by the Federal Guidelines, and to assess patient recall of this information.

Methods

Five health departments in the State of Maryland were asked to participate in a direct observation study of providers' practices in routine STD visits. One health department declined and another was dropped because of logistical difficulties. Observations were made in six clinics, representing three different county health departments between November 1985 and April 1986. Seventy-nine patients were enrolled in this study; this analysis is based on 60 patients for whom complete data were available. The patient sample was predominantly male (71 percent), and racially mixed (45

Increase in Condom Sales following AIDS Education and Publicity, United States

JOHN S. MORAN, MD, HARLAN R. JANES, THOMAS A. PETERMAN, MD, MSc, AND KATHERINE M. STONE, MD

Abstract: Data from a national probability sample of drug stores show that condom sales rose from 240 million annually in 1986 to 299 million in 1988. The greatest increase occurred in 1987 after the Surgeon General's report on AIDS was released. Sales of latex condoms with spermicide rose 116 percent. Sales of other types of condoms increased less. These data suggest that Americans are using more condoms and probably more effective condoms in response to AIDS education. (Am J Public Health 1990; 80:607–608.)

Introduction

In his report on the acquired immunodeficiency syndrome (AIDS), the US Surgeon General advised persons whose sex partners may have been exposed to the AIDS virus to always use a condom during sexual intercourse.[1] An extensive public health campaign has since promoted condom use by persons who have sex outside of mutually monogamous relationships. Latex condoms, especially those containing spermicide, are believed to provide more protection than natural membrane condoms and have been the most highly recommended.[2]

Given the extensive public education effort and attendant publicity, we wondered if Americans were using more condoms. In a 1988 survey of urban teenage males, 58 percent reported using condoms during their last sexual encounter, compared to only 21 percent in 1979.[3] We analyzed a more objective measure, condom sales trends, to see how they have changed during the HIV (human immunodeficiency virus) epidemic.

Methods

Drug stores condom sales were estimated from bimonthly sales audits conducted by Nielson Marketing Research (Northbrook, IL). This national probability sample is stratified by size of store (four strata), geographic region (10 strata) and relative urbanization of the county where the store is located (four strata). Approximately 550 drug stores are audited, which compose 1 percent of drug stores and account for 2 percent of drug store sales. The same stores are audited every two months, making the system very sensitive to trends.

Condom sales in areas with a high incidence of AIDS were compared with sales in the remaining US. High incidence areas were defined as the television markets of the following metropolitan areas: Atlanta, Houston, Los Angeles, Miami-Fort Lauderdale, New York, San Francisco, and Washington, DC. These areas encompass one-fifth of the US population, one-third of all condom sales, and two-thirds of all AIDS cases. To reduce the tendency of seasonal variations in sales to obscure short-term trends, we compared sales for each two-month period with sales in the same period a year earlier.

To gauge condom publicity over time, we counted monthly condom citations using three indices: Newspaper Abstracts (University Microfilms International, Inc., Ann Arbor, MI), National Newspaper Index and Magazine Index (both produced by Information Access Company, Foster City, CA). All three showed the same pattern; only Newspaper Abstracts data are shown.

Results

Drug store condom sales grew slowly from 1984 to 1988 except for a 20 percent increase between 1986 and 1987 (Table 1). Sales of some styles grew more rapidly than others. Between 1986 and 1988, sales of *all* latex condoms increased 25 percent (226.1 to 283.4 million). The biggest percentage growth was in latex condoms with spermicide which increased 116 percent (23.2 to 50.1 million). Latex condoms without spermicide increased 15 percent (202.9 to 233.3 million). Natural membrane condom sales increased 7.8 percent (14.4 to 15.6 million).

Sales increased both in areas with a high incidence of AIDS and in the remaining US between 1986 and 1988 (Figure 1). Sales in the high incidence areas were growing throughout 17 of the 18 two-month periods. In contrast, sales were not growing in the remaining US until the beginning of 1987, and sales stopped increasing in July-August 1988. In both areas, condom sales grew rapidly throughout 1987 and early 1988 following the release of the Surgeon General's report in November 1986. Media attention to condoms also increased. Condoms were rarely mentioned before the report, but were increasingly cited in articles, editorials, and cartoons thereafter, reaching a peak in February 1987, when 182 items appeared in the 19 newspapers indexed by Newspaper Abstracts. (Forty percent of the February items concerned the controversy over whether condom advertisements were appropriate for television.) Throughout the remainder of 1987

TABLE 1—Annual Condom Sales in US Drug Stores, 1985–88, and Percent Change from Previous Year

	Sales in Millions (% change)			
	Latex			
Year	With Spermicide	Without Spermicide	Natural Membrane	Total

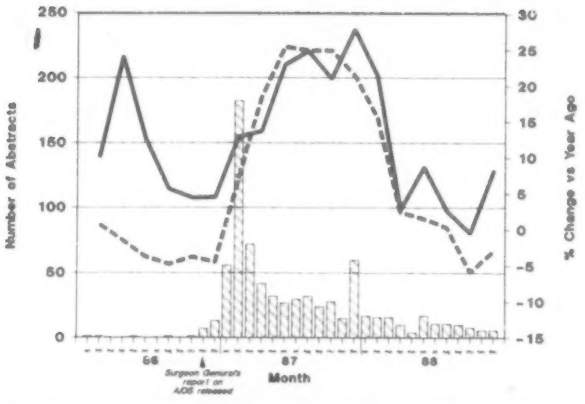

FIGURE 1—Annual Percentage Change in Condom Sales in Drug Stores in Seven Areas with High Incidence of AIDS (solid line) and remainder of United States (broken line) and Number of Newspaper Abstracts Mentioning Condoms (bars), 1986–88.
NOTE: Percent change in sales from the same period one year earlier are shown for two-month periods.

and 1988 media attention was greater than in 1986, but slowly diminished.

Discussion

The 20 percent increase in drug store condom sales in the year following the Surgeon General's report suggests that Americans responded to his message. In comparison, cigarette sales fell only 2.4 percent in the year following the Surgeon General's first report on smoking and health.[4]

The increase in sales was probably related to the recommendation that condoms be used to prevent HIV transmission. Sales of latex condoms, which were recommended for AIDS prevention, increased more than sales of natural membrane condoms. In addition, the greatest percent increase was in latex condoms with spermicide which cost more but may provide additional protection. The overall increase in drug store condom sales between 1984 and 1988 was 26 percent.

How much of the increase was for disease prevention? To answer this, we must estimate the proportion of condoms purchased primarily for contraception. According to studies of US women between 18 and 44 exposed to the risk of unintended pregnancy,[6] 14 percent of married women relied on condoms in 1982, making up 73 percent of the condom users in this population; in 1987, the proportion of married women using condoms was almost unchanged at 15 percent, suggesting that married women choosing condoms are mainly concerned with contraception, not disease prevention. In contrast, the percentage of unmarried women choosing condoms increased from 9 percent in 1982 to 16 percent in 1987, probably reflecting concerns about disease.[6] If all unmarried women choosing condoms do so for disease prevention, then there was a 78 percent increase in women using condoms for disease prevention.

How do sales compare with the number needed if all Americans who have intercourse outside of mutually monogamous relationships use condoms with every act of intercourse? Approximately 23 million Americans reported having more than one sex partner per year and 120 million reported a single sexual partner.[5] However, we do not know how many relationships are mutually monogamous or how often any of these people have intercourse. This lack of knowledge of Americans' sexual activity make it impossible to estimate the number of condoms needed to protect Americans from AIDS.

Other studies have shown increases in self-reported condom use among particular groups. However, behavior self-reports may be more affected by educational messages than behavior itself. Although this study has the advantage of using an objective measure of behavior, we have no evidence that the condoms purchased are actually used. Furthermore, the sales data are from drug stores only; condoms sold elsewhere or distributed free-of-charge are not included. Also, sales data give no information on who buys condoms or why.

This nationwide study of condom purchasing and other repeated surveys of sexual behavior show encouraging trends. But some populations are not being reached adequately. Despite the increase in sales and reported use of condoms, syphilis rates increased 25 percent between 1986 and 1987, with urban areas having the highest rates.[7] We need to learn how to increase the use of condoms among those who are at greatest risk of disease.

Car Design and Risk of Pedestrian Deaths

LEON S. ROBERTSON, PHD

Abstract: Fatal pedestrian injury rates by cars with relatively sharp front-corner designs were compared to such rates by cars of similar-size with relatively smooth front-corner designs. The relative risk of death by front-corner impact was 26 percent greater among the sharp-cornered cars. Pedestrian death rates from impact with other points on the cars and insurance claim frequencies among the studied cars were similar between the two sets of cars. (*Am J Public Health* 1990; 80:609–610.)

Introduction

In 1967, William Haddon, Jr., sent letters to 38 manufacturers of motor vehicles and their suppliers with pictures of designs that increased the severity of collisions with pedestrians.[1] In 1971, Haddon showed a committee of Congress the design of front ends of cars that resembled the design of ancient weapons—spears and battle axes.[2]

Despite Haddon's warnings, in the 1980s a number of large cars featured sharp protrusions as part of the design of their front corners. In impacts with pedestrians, these designs would be expected to increase the severity of injury because of their shearing effect.[3] The purpose of the research reported here was to investigate the extent to which such designs were associated with increased risk of pedestrian mortality in comparison with similar-sized cars that had relatively smooth front-corner designs.

Methods

A trade magazine with pictures of new cars introduced for sale in the United States during the model years 1980 through 1985 was examined to identify those that had sharp edges on their front corners.[4] Since all of the vehicles with sharp corners weighed more than 3,000 pounds, all cars from the same manufacturers that had relatively smooth front corners and weighed more than 3,000 pounds were chosen for comparison. The compared vehicles are listed in the Appendix.

Data on pedestrian fatalities in which the pedestrians were struck by the listed cars during the calendar years 1982–87 were obtained from the Fatal Accident Reporting System (FARS) computer files. These files contain data on virtually every fatal motor-vehicle injury in the US. The data include clock position of principal impact, eleven and one o'clock for front-corner impacts. Rates of pedestrian fatalities per vehicle years of use by principal point of impact were calculated using sales data[4] to estimate vehicle years of use.

To estimate vehicle use of vehicles sold during the calendar years of the study as accurately as possible, monthly sales data were used to calculate months of use during the year in which a given model was sold. The total years of use was thus the number of months from the sale in the first year divided by 12 plus the total number sold in the year times the number of years subsequently through 1987.

The rates of pedestrian deaths per 100,000 years of use from front-corner impacts and impacts at other points on the vehicles of the sharp-cornered relative to the smooth-cornered vehicles were compared. If differences in the pedestrian death rates in front-corner impacts of the two sets of vehicles were due to differences in driver factors, vehicle factors other than front-corner designs, or use in different environments, a similar difference in non-corner impacts should be found between the two sets of vehicles. There is no reason to believe that other risk factors would increase front-corner impacts but have no effect on pedestrian impacts at other points on the same vehicles.

Also, if the sharp-cornered vehicles were driven differently or had more defects that would increase their risk of collisions generally relative to the comparison vehicles, the insurance claim frequency for those vehicles should be higher. Therefore, the average insurance claim frequency of the two sets of vehicles was also compared using published data from insurance claims.

Results

The numbers of pedestrian deaths and deaths rates per years used in front-corner and other-point impacts of the cars with relatively sharp and relatively smooth front corners are presented in Table 1. The death rate of the relatively sharp-cornered cars in front-cornered impacts was 1.26 times that of the relatively smooth-cornered cars (95% CI = 1.05, 1.50). Thus the sharp-cornered vehicles had an average of 26 percent greater risk of pedestrian deaths in front-cornered impacts. In impacts with other points on the vehicles, the sharp-cornered cars had a relative risk of 0.98 compared to the smooth-cornered cars (95% CI = 0.86, 1.11), that is, virtually the same rates in non-cornered cars.

TABLE 1—Relative Risk of Fatal Pedestrian Injury By Front-corner Design and Point of Impact—Large US Cars, 1982–87

Front-Corner Design	Deaths		100,000 Years Used	Death Rate		Relative Risk	
	Front Corner	Other		Front Corner	Other	Front Corner	Other
Smooth	589	1403	641.9	0.91	2.19	1.00	1.00
Sharp	160	296	138.8	1.15	2.13	1.26	0.98

95 percent confidence intervals (log odds method) (Front corner 1.05, 1.50) (Other 0.86, 1.11).

The insurance claim data were relative claim frequencies standardized so that the all-car average equals 100.[6] The smooth-cornered cars in this study had an average relative claim frequency of 86. The claim frequencies of the sharp-cornered cars had an average of 87, little different from the smooth-cornered cars' average.

Discussion

As physics and biomechanics predict, moving objects with sharp points do more damage when they strike people than do smooth objects.[3] The 26 percent average greater risk of fatal pedestrian injury from sharp-cornered compared to smooth-cornered cars is consistent with that knowledge. The rate of fatal non-corner impacts, comparing the same vehicles, were similar, suggesting that the major difference among the vehicles in risk to pedestrians is the sharpness of their front corners. The average insurance claim frequency of the two sets of vehicles were nearly the same. Therefore, it is unlikely that driver, environmental, or other vehicle factors accounted for the differences in pedestrian death rates from front-corner impacts.

Vehicle manufacturers often cite costs as the reason for refusing to design and build safer vehicles. Yet the sharp corners on the vehicles in this study require more material than would smooth corners.

The lack of difference in rates of non-corner impacts does not necessarily mean that other points on the vehicles were optimally designed. They were just not different, on average, among these two sets of vehicles. Low bumpers and hoods in combination with smooth, sloped hoods and energy absorbing material in the bumpers and windshield rims are the most efficacious designs.[7]

APHA Epidemiology Section Invites Abstracts for Poster Session

The Epidemiology Section of APHA will again be sponsoring a "Late-Breaker" poster session at the upcoming annual meeting. The session will take place on Wednesday, October 3, 1990, 12:30–2:00 p.m. Work completed in 1990 is eligible for consideration. Abstracts must be *received* by September 7 at the address given below. Students and recent graduates are particularly encouraged to submit abstracts. Submit an abstract of less than 200 words (any format) and a return envelope to:

Males' Use of Public Health Department Family Planning Services

MICHAEL GLASSER, PHD

Abstract: Information was obtained from over 200 males visiting a family planning service either to obtain free-of-charge condoms or incidental to accompanying their female partner. The former group was younger and more likely to reside near the health department; over 40 percent of this group used the health department as sole condom source. Both groups indicated willingness to share in costs for male services. Future programs need to more effectively plan public health family planning for these males. (*Am J Public Health* 1990; 80:611–612.)

Introduction

A pilot study, summarized in detail elsewhere, presented the responses of 70 male clients to a brief questionnaire concerning sexual activity, contraceptive use, and health department visits. Results indicated the health department was serving a substantial population of males and was a central and often exclusive source of condoms. Methodologically, under conditions of anonymity, males were willing to answer questions regarding family planning and sexual activity.

The present research was conducted at the Winnebago County Public Health Department in Rockford, Illinois (population 139,712), with 279,514 living in the Standard Metropolitan Statistical Area. The family planning service of the health department has focused in the past nearly exclusively on female clients, consistent with national trends. Danielson, *et al*, point out that formulas for fund allocation are derived primarily from the number of women in need of services as well as actual number served; men are considered only more peripherally, if at all.

In the present case, a condom distribution service for males was made possible through health department commitment to providing total services related to birth control needs. The family planning clinic set up a distribution desk for condoms where males could request the contraceptive at specific times. Contraceptive availability was advertised in brochures and in the newspaper. Males had to be at least 13 years old to receive condoms. They also received literature regarding family planning and contraceptive use. This study was designed to further provide information on males' use of these services.

Method

Results of the pilot study revealed that there were two different "groups" of males at health department family planning: males using the free-of-charge condom service (Group C) and males attending the family planning visit of their female partner (Group P). We obtained information from both groups.

Sampling focused on units of time broken down into three parts for each day that the condom distribution service and family planning service were open over a six-month data collection period. Nearly 30 percent of time periods were sampled. During these periods, all males requesting condoms or visiting with their partner were asked to complete a questionnaire or consent to an interview. At the time of this study, the Group P males were specifically visiting with their partners and did not request condoms from the distribution service during that visit. While some males visited family planning more than one time during the study period, they completed only one questionnaire or interview.

Results

A total of 207 males responded (74 percent from Group C and 78 percent from Group P). For Group C, there were 157 separate contacts during the study period, for Group P 144 encounters; altogether, an estimated 2,007 (±46 at 95% confidence intervals = 1961, 2053) contacts with males in one year.

Group C males using the condom service were younger than Group P males, less likely married, had a lower educational level, and lived nearer the health department. They reported a younger age of first intercourse—12.7 compared to 14.4 years. Over 47 percent of Group C had been sexually active by 12 years old compared to 26.2 percent of Group P. At first sexual encounter, nearly 60 percent of all males reported *not* using contraception.

When asked who has primary contraceptive responsibility, Group P males were more likely to indicate both the man and woman and relied less on condoms and more on other measures of birth control, such as the pill. Nearly one-half of Group C males reported condom use for two or more years but 15 percent used condoms for three months or less; over 45 percent indicated always using condoms while nearly 30 percent reported frequency of use as "usual."

Nearly two-thirds of Group C males were repeat visitors to the service, and over 40 percent had visited within one month (Table 1). Almost 42 percent reported the service as sole source for condoms. Main reasons for use were the service was free, friend's suggestion, and no questions asked. Nearly 70 percent visited the service with a friend.

For Group P males, about 60 percent were accompanying their partner to family planning for the first time. The males were there primarily to provide emotional support, give transportation, and be a part of the family planning process. Nearly one-fourth of Group P males had used the condom distribution service.

When asked if they would buy condoms from the service if necessary or share in expenses for services, 72 percent of Group C and 77 percent of Group P males replied yes (Table 2). Both groups reported satisfaction with health department services. The Group C males were a little more likely to indicate interest in additional services, including medical examinations, sexually transmitted disease (STD) programs, and support for adolescent fathers (66 vs 55 percent).

Discussion

The health department provides access to birth control

both for men wanting condoms and those whose partners are seeking family planning. For males using the condom distribution service, nearly one-half reported exclusive use of condoms, two-thirds made more than one visit to the health department, and 40 percent viewed the health department as sole condom source.

Many Group C males were "repeat" service users. Of the 1,047 projected visits, one-third (346) were first visits. Although it is not clear how many different males are represented in the 701 remaining visits, it is apparent that a large proportion of males could be classified as regular clients.

Group P males comprise a population "in place" to benefit from public health services. They expressed interest in obtaining general as well as family planning services and seem relatively "untapped" as a target of programming.

Study limitations were that data were collected at one time rather than longitudinally and the focus was on one facility. Still, it was evident that there was a high frequency of male contacts, if not direct service utilization. In relation to Title X and to health care in general, it appears there is a large population that could be brought more formally under the "umbrella" of family planning.

ACKNOWLEDGMENTS

The author would like to thank Dr. Joseph Orthoefer, Susan Carter, and Craig Campbell for their contributions in data collection for this study. The research was supported in part by grant R23 FP00114-01 from the Office of Population Affairs. An earlier version of this paper was presented at the 49th Annual Meeting of the Illinois Public Health Association, Chicago, Illinois, 1989, and was winner of the Research Award for Technical Papers.

The Prevalence of Severe Mental Disorder Among Male Urban Jail Detainees: Comparison with the Epidemiologic Catchment Area Program

LINDA A. TEPLIN, PHD

Abstract: This paper presents the prevalence rates of schizophrenia and major affective disorders by age and race among a random sample of male jail detainees. Subjects were administered the National Institute of Mental Health Diagnostic Interview Schedule (NIMH-DIS). The jail prevalence rates were then compared with general population data from the five-city Epidemiologic Catchment Area program using difference of proportion tests and loglinear analysis. After controlling for demographic differences between the jail and five-city samples, the jail prevalence rates were still two to three times higher than those in the general population. These findings suggest several public policy modifications concerning the psychiatric management of our burgeoning jail population. (*Am J Public Health* 1990; 80:663–669.)

Introduction

Mental health professionals speculate that the jails have become a repository for the severely mentally ill. Often referred to as the criminalization hypothesis, this trend is thought to be the unintended consequence of policy modifications, e.g., deinstitutionalization and more stringent commitment criteria.[1–3] Of particular concern are minor offenders (e.g., shoplifters) who could be treated in the mental health system but are instead managed by the criminal justice system. Criminal processing of the mentally ill may be most common among the individuals of the underclass because they have less access to treatment, fewer treatment alternatives, and less social support than wealthier persons.[4]

Jails, rather than prisons, are the critical point to gather psychiatric epidemiological data. Jail populations include detainees awaiting trial and convicted offenders serving sentences of less than one year, while prisons contain only convicted criminals serving longer sentences. Prison samples are biased because inmates are often diverted to forensic psychiatric facilities prior to conviction or imprisonment; prevalence rates of severe disorders in prisons* appear to be lower than those in jails[2] and those in the general population.[5,6]

The Appendix displays the findings of previous prevalence studies of mental illness among jail populations.[7–24] Interestingly, the studies listed show no increase in prevalence rates over time, and little consistency across studies. The tremendous variation in prevalence rates may be explained, in part, by three major methodological limitations:

- *Sample Selection*—To date, only four studies have used random samples.[11–13,23] One study used volunteers,[20] resulting in a plethora of potential biases. The most common type of study includes only persons who are referred for a mental health evaluation, and is obviously biased.
- *Measurement*—The variability in prevalence rates may be a result of the unknown reliability of the instrumentation used in many investigations. Since many studies used unspecified diagnostic criteria and/or nonstandardized instruments,[11,14,16] the diagnostic process is probably inconsistent across samples.
- *Sample Size*—Psychotic disorders have an extremely low base rate, between 1–2 percent.[5,6] The low base rate requires a relatively large sample size to generate accurate prevalence statistics.[25] No study incorporating a random sampling strategy used a large enough sample size.

None of these studies compare the jail prevalence rates with those in the general population. Moreover, because jail detainees are disproportionately young and minority group members[26]—characteristics correlated with severe mental disorder[27]—any comparison with baseline data must control for the jail's demographic composition.

The dearth of reliable psychiatric epidemiological data is critical because of the correctional system's overwhelming growth: between 1978 and 1983, the jail census rose by 40 percent, and by 1987, it increased by another 28 percent.[28–30] Research and intervention at the jail level are particularly important because not only are many jail detainees in need of ameliorative treatment, they are captive and physically amenable to intervention.

This paper provides an accurate estimate of severe mental disorder among male jail detainees in Cook County, Illinois, and compares the prevalence rate to that of the general population.

Methods

Subjects

Jail subjects studied were a stratified random sample (approximately one-half misdemeanants, one-half felons) of male detainees who entered Cook County Department of Corrections in Chicago, Illinois, directly from pretrial arraignment between November 1983, and November 1984 (N = 728). Persons charged with both misdemeanors and felonies were categorized as felons. Data were subsequently weighted to reflect the actual composition of misdemeanants and felons. The jail receives approximately 60,000 admissions per year[31] and is demographically similar to other large urban jails on such variables as race and age.[32] The size of the facility ensured adequate subject availability.

By assuming a binomial distribution for the frequencies of occurrence or non-occurrence, this sample size allows us to reliably detect events which have a base rate in the general population of less than 1 percent.[33]

The age range of subjects was 16–68 years, mean and median age of 26.3 and 25.0 years, respectively; 57.4 percent were employed at the time of arrest. The racial composition was predominantly Black (80.8 percent); 6.5 percent of the sample were Hispanic, 12 percent were other Whites, and the remaining 0.8 percent were largely Asian or American Indian. Educational level ranged from two to 16 years of schooling, mean 10.6 years, median 11.0 years. The sample demographic characteristics (including the skewed racial/ethnic breakdown) reflect the demographic composition of the Cook County Jail.

Procedures

All detainees, excluding persons with gunshot wounds or other traumatic injuries, were part of the sampling pool. Personnel at the jail referred all persons targeted for participation in the project, regardless of their psychiatric morbidity, state of drug or alcohol intoxication, potential for violence, or fitness to stand trial. Subjects were selected via random numbers as they waited to be processed in the jail intake area. To ensure that the sample contained approximately equal numbers of misdemeanants and felons, the interviewers alternated between them in the sampling process.

Interviewers were clinical psychologists who had extensive training in interviewing techniques, psychopathology, and the data collection instrument. Interviewer consistency was scrupulously maintained after the initial three-month training period via mock interviews with live subjects, spot checks, and videotape training. Detainees who consented to be subjects were paid $5 which was mailed to an address of their choice. Of 767 subjects approached, 35 (4.6 percent) refused to participate. The low refusal rate was probably due to the detainees' viewing the research project as a way to avoid the crowded and dismal conditions of the regular intake area. Four other subjects were excluded: two "duplicate" subjects (they were re-arrested and randomly selected again) and two others who appeared to be confabulating their responses. Thus, the final N was 728.

Subjects were interviewed in a soundproof, private glass booth within the jail intake area using the National Institute of Mental Health Diagnostic Interview Schedule (NIMH-DIS).[34] Empirical tests have documented the reliability of the NIMH-DIS in both institutionalized samples and the general population[35–38] (in contrast, see the report by Anthony, *et al.*[39] The DIS systematically differentiates between disorders that were ever manifest, even if currently remitted (lifetime disorders), and disorders in which symptoms have been recently experienced (current disorders).

The NIMH-DIS provides diagnostic categories rather than global psychopathology scores. DSM-III diagnoses are scored from the interview data by a computer program written expressly for this purpose.[40] Because of subject variance over time and the rarity of many disorders, it is difficult to assess the reliability and validity of psychiatric assessment instruments such as the DIS.[41] Nevertheless, a reliability check of twenty pairs of interviews found 93 percent agreement across all diagnoses; 85 percent were given nearly identical profiles. The interview lasted between one and three hours, depending on the number of positive symptoms of the detainee.

The baseline (general population) data were obtained from the NIMH Epidemiologic Catchment Area program[42] which, also using the NIMH-DIS, calculated the prevalence rates of mental disorders in five cities: Baltimore (n = 3,481), New Haven (n = 5,034), Los Angeles (n = 3,131), Raleigh-Durham (n = 3,921), and St. Louis (n = 3,004).[5]

Because the jail sample was male, female subjects were eliminated from the comparison data. We also omitted all Hispanics (as well as other subjects who were neither Black nor White) from both data sets because there was an insufficient number of Hispanic jail detainees to include in the analysis (n = 47). Since the five-city sample excluded persons under the age of 18, we eliminated 53 subjects under that age from the jail sample in the comparison. Because almost all the jail sample were under age 60, we also excluded subjects over age 60 from the comparison. The final sample includes 627 jail detainees and 3,481 from the general population in the five cities: Baltimore, n = 825; New Haven, n = 748; Los Angeles, n = 431; Raleigh-Durham, n = 832; and St. Louis, n = 818. The complex sampling design of the five-city sample[43] required adjustment of the variances and standard errors presented in this paper using design effects estimated with Taylor Series Linearization provided by the National Institute of Mental Health.[44]

We calculated the prevalence rates of three disorders: major depressive episode, manic episode, and schizophrenia (including schizophreniform disorder). For each disorder, separate analyses were conducted to differentiate between "current" (defined as symptomatic within two weeks of the interview) and "lifetime" diagnoses. We conformed with the Epidemiologic Catchment Area study in that the disorders are not mutually exclusive: a subject could meet criteria for more than one disorder.[45]

In order to attain adequate statistical power for the jail-general population comparison, the data from the five cities needed to be combined. Before doing so, we compared the prevalence rates of each disorder across the five cities. This precautionary measure ensured that any observed differences between the jail and the general population data were not merely an artifact of the idiosyncratic characteristics of one or two of the cities. A loglinear analysis indicated that there were no significant or substantial dissimilarities in prevalence rates across the five cities (data available on request to author).

Results

Tables 1 and 2 show the prevalence rates with their standard errors, differences between the jail and the five-city sample, and the ratio of the differences in prevalence rates to the standard error of the difference (differences of proportions test[46]) for current and lifetime disorders, respectively. The uneven partitioning of age is dictated by the limited number of jail detainees over age 32 (n = 117). We did not simultaneously cross-classify by race and age because the resulting decrease in cell size would reduce power to an unacceptable level. The tables do not present data on socioeconomic status (SES) because the only SES indicators used in the five-city general population study (income and occupation) measure the individual's *achieved* status. These variables are inappropriate for this analysis because they have inconsistent bidirectional and temporal effects on the dependent variable. Low income and unemployment may either precede or result from severe mental illness.[47,48] Race is an indirect indicator of SES because of the strong correlation between these two factors.[49,50]

Tables 1 and 2 show that, overall, prevalence rates of current and lifetime major depression, mania, and schizophrenia, and "any severe disorder" (that is, any of the three

disorders) are significantly higher in the jail sample than in the five-city sample. The overall prevalence rates for current disorders are 1.24 percent to 4.52 percent higher among jail detainees than in the five-city sample; for lifetime disorders, the rates are 2.01 percent to 5.07 percent higher in the jail sample. In general, the differences in both current and lifetime prevalence rates between the jail and five-city samples hold when controlling for race. Except for current schizophrenia among Whites, and lifetime schizophrenia among both Whites and Blacks, the differences between the jail and the five-city sample remain statistically significant for Blacks and Whites, ranging from 1.04 percent (current mania among Blacks) to 8.43 percent (current major depression among Whites). The differences between the jail and the five-city sample are somewhat less robust when controlling for age, but this may reflect the small sample sizes.

The difference of proportions test (Tables 1 and 2) is less powerful with low prevalence rates than other techniques, e.g., loglinear analysis.[51] Given the limitations of the difference of proportions test, we reanalyzed the data using hierarchical loglinear modeling[52] (Table 3). This technique enables us to test the differences between the jail and five-city samples while holding both age and race constant.

Table 3 reports the parameters, the ratio of parameters to their standard errors (roughly equivalent to the likelihood ratio chi-square test), and model statistics for the final loglinear models for each current and lifetime diagnosis. Empty cells were set to .05, rather than the less conservative technique of setting them to structural zeros and adjusting degrees of freedom.[53] Notice that for each of the eight models, the site (jail/five-city sample) by diagnosis (present/absent) effect is retained and is in the hypothesized direction. In other words, we can reject the hypothesis of homogeneity for all current and lifetime disorders. In all cases, the coefficient for a diagnosis by site interaction exceeds its standard error by at least 2.58, or with a probability of less than .01. The analysis thus strongly supports our hypothesis: the prevalence rates of major depression, mania, and schizophrenic disorders are significantly higher in the jail than in the five-city sample, and are not an artifact of race or age differences between the two samples.

Discussion

This study provides reliable data concerning the relative prevalence of severe mental disorder among urban jail detainees in Cook County, Illinois, and the five-city Epidemiologic Catchment Area sample of the general population: for all race-age subgroups, the observed jail rates of schizophrenia, major depression, and mania were two to three times higher than in the general population. Moreover, these prevalence rates likely underestimate the true prevalence of mentally ill persons who are processed through the criminal justice system; samples obtained at the jail level omit all persons who are arrested but not incarcerated because they are diverted to a mental health facility during their pretrial hearing.

Our results do not enable us to ascertain whether mental disorder is a causal determinant of a criminal career, or merely a frequent trait among these offenders. Comparison with similar studies is of little utility. As demonstrated in the Appendix, their methodological limitations do not permit us to infer with any certainty whether our prevalence rates are higher than those found in prior studies. Our data thus provide necessary, but not sufficient, evidence that the mentally ill may be diverted into the criminal justice process.

In their exhaustive review of the literature, Monahan and Steadman[27] concluded that the apparently greater prevalence

of mental disorder among offenders disappears when sociodemographic factors are taken into account. In this study, however, the differences between the jail and general population persisted even after controlling for race and age.

It is also interesting to note that the observed ratio of current jail rates to current population rates is substantially higher than the comparable ratio of lifetime rates. This finding lends further support to the criminalization hypothesis because we know the arrest occurred during a period of active illness. Mentally ill persons with co-occurring substance abuse and personality disorders may be the most vulnerable to arrest because few treatment alternatives are available.**,[4] Clearly, further research is needed to disentangle the relationship between mental disorder and criminality, as well as to ascertain if mentally ill persons who are more appropriately treated within the mental health system are being funneled into the criminal justice system.

The finding that over 6 percent of all incoming jail detainees were suffering from a "current" psychotic illness suggests several public policy implications.

First, since disorders such as schizophrenia, major depression, and mania require immediate attention, jails must routinely screen all incoming detainees for severe mental disorder.[54] Interestingly, although the courts mandate that jails conduct routine mental health evaluations,[55–57] many jails do not do so.[58] The relative paucity of routine evaluation programs in jails is probably due to insufficient fiscal and mental health resources, as well as a dearth of screening instruments that are appropriate for the jail setting. Recent developments in screening techniques designed to be used within correctional settings[59] are likely to aid in the detection of mental illness. Jail administrators should incorporate these or similar instruments into their routine intake process to ensure that severely ill detainees will be detected and treated.

Second, the prevalence of detainees who are actively psychotic suggests that jail administrators must negotiate programmatic relationships with mental health facilities. Unfortunately, although the courts have stipulated that mentally ill prisoners must receive treatment for mental disorders,[60–62] many jails, particularly those in rural areas, have no mental health liaison.[63] Detainees can either be treated "in house," or referred outside.[64] Whichever system is used, it must be designed to minimize bureaucratic impediments to treatment.

Third, in accordance with the American Bar Association Mental Health Criminal Justice Standards,[65] mentally ill detainees who have committed minor crimes, e.g., trespassing and disorderly conduct, should be diverted to the mental health system. Clearly, persons whose offenses are more symptomatic of mental illness than of criminality should be treated as disordered rather than disorderly.

In sum, our results cannot be interpreted as evidence that the mentally ill are increasingly subject to incarceration. Nevertheless, the data document that the prevalence rate of severe mental disorder is significantly higher in a typical urban jail than in the general population. Additional epidemiological work is needed to ascertain the extent to which this finding is generalizable to other geographical areas. In accordance with court rulings, and in view of the number of severely disturbed detainees in our jails, we must allocate sufficient resources and develop and implement innovative treatment programs so that the mentally ill in jail may be treated expeditiously and in the most humane manner possible.

ACKNOWLEDGMENTS

This work was supported by Public Health Service Grant MH37988. I would like to thank Dr. Karen Mirsky Abram and Nancy Pruett for their insightful comments on an earlier version of this paper and Giovanni Moneta for his initial work on the analysis. Dr. Gary M. McClelland provided extensive advice and assistance in preparing and analyzing these data. Laura Coats was invaluable in the editing and preparation of the manuscript. Drs. Lee Robins and William Eaton, and Don Rae, MA, were instrumental in preparing the ECA data.

APPENDIX

The Prevalence of Mentally Disordered Persons in Jails: A Summary of the Most Recent Research

Study	Description of Sample	Findings
Bolton[7] 1976	N = 1,084 (gender unknown) from 5 county jails	6.7% psychotic
Petrich[8] 1976	N = 539 referred for evaluation; 80% male; 42% felons	49% psychotic 10% depression
Petrich[9] 1976	N = 122 referred for evaluation; 84% male; 80% felons	29% schizophrenia 12% depression 6% mania
Piotrowski, Losacco, & Guze[10] 1976	N = 50 selected from those referred for evaluation; 86% male	22% schizophrenia 10% bipolar
Swank & Winer[11] 1976	N = 445 referred for evaluation; gender unknown; 41% felons N = 100 randomly selected; gender unknown; 71% felons	26% psychosis 5% psychosis
Kal[12] 1977	N unknown; random sample	Any DSM-III diagnosis:50% females; 63% males
Schuckit, Herrman & Schuckit[13] 1977	N = 100 males randomly selected; no felony convictions; no current drug charge	3% affective 48% any diagnosis
Nielson[14] 1979	N unknown; sample referred	24% psychosis
Monahan & McDonough[15] 1980	N = 632 referred for evaluation; 82% male; 55.5% misdemeanants	32% schizophrenia
Whitmer[16] 1980	N = 500 (gender unknown) "in need of treatment"	Averaged 3 prior psychiatric hospitalizations
Morgan[17] 1981–2	N unknown; sheriff's perceptions of mental illness	Estimates from 4–50%
Lamb & Grant[18] 1982	N = 102 males; random sample from referrals for evaluation; drug/alcohol excluded; 53% felons	75% schizophrenia 22% affective disorder
Lamb & Grant[19] 1983	N = 101 females, random sample from referrals for evaluation; drug/alcohol excluded; 37% felons	59% schizophrenia 35% affective disorder
Ninzy[20] 1984	N = 50 volunteers; 74% males	26% psychosis
Virginia DMH[21] 1984	N = 171 "mentally ill" as identified by staff	40% schizophrenia 21% mania
Glaser[22] 1985	N = 50 referred for evaluation; Australians (gender unknown)	48% schizophrenia 16% affective disorders
Guy, Platt, Zwerling & Bullock[23] 1985	N = 486 males randomly selected; 96 given diagnostic interview	12% schizophrenia 4% affective disorder
Valdiserri, Carroll, & Hartl[24] 1986	N = 769 referred for evaluation; 86% male	17% psychotic 5.5% predicted morbidity rate: total jail

Case-Control Study of Lung Cancer and Truck Driving in the Teamsters Union

N. Kyle Steenland, PhD, Debra T. Silverman, PhD, and Richard W. Hornung, PhD

Abstract: We conducted a case-control study of lung cancer deaths in the Teamsters Union to compare the risk of different occupations within the teamsters, after controlling for smoking and other confounders. Occupations with no presumed exposure to diesel fumes were used as the nonexposed group. The study population consisted of 996 cases and 1,085 controls who had died in 1982-83 after applying for pensions. Next of kin provided information on smoking, work history, and other potential confounders. Work history data were also obtained from the Teamsters Union. While no single job category had a significant excess risk compared to the non-exposed group, certain sub-groups were elevated. The odds ratio for those with long-term employment as long-haul truckers after 1959 (an approximate date for the introduction of diesel engines) was 1.55 (95% CI: 0.97, 2.47). Long-term drivers of primarily diesel trucks had an odds ratio of 1.89 (95% CI: 1.04, 3.42). Overall, our results suggest that diesel truck drivers have an excess risk of lung cancer compared to other teamsters in jobs outside the trucking industry. However, our findings were not uniformly consistent and our data have many limitations, the most important of which is the lack of data on exposure to diesel fumes. (*Am J Public Health* 1990; 80:670–674.)

Introduction

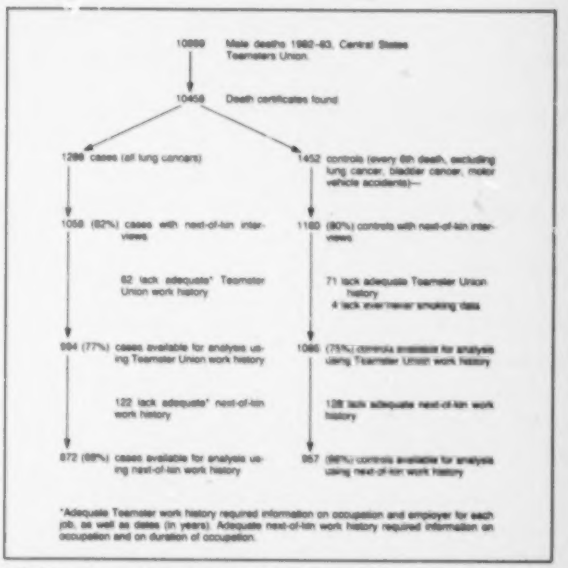
Inhaled diesel exhaust causes lung tumors in rodents,[1] and there is limited industrial hygiene data showing that truck drivers are exposed to diesel exhaust.[2] Recent human studies[3,4] also have indicated an excess lung cancer risk for diesel-exposed workers, after controlling for smoking. To test the hypothesis that truck drivers have an excess risk of lung cancer, we conducted a case-control study of lung cancer in the Teamsters Union. The risk for men in different occupations within the trucking industry was compared to that of men outside the trucking industry in jobs with no presumed diesel exposure. We had no direct data on level of exposure to diesel exhaust. A separate National Institute for Occupational Safety and Health/National Cancer Institute (NIOSH/NCI) project is now in progress to measure current exposure to diesel exhaust in the trucking industry, and to estimate historical exposures.

Methods

Study Population and Data Sources

Cases and controls were selected from the 10,699 male decedents from the Central States Teamsters files who had filed claims for pension benefits (requiring 20 years tenure in the union) and who had died in 1982 and 1983. We obtained death certificates for 10,485 (98 percent) of these men. Cases were all deaths from lung cancer, coded as ICD 162 or 163 for underlying or contributory cause on the death certificate (n = 1,288). Controls (n = 1,452) were every sixth death from the entire file (sorted by Social Security number), excluding deaths from lung cancer, bladder cancer, and motor vehicle accident.

Next of kin were questioned in detail on work history and potential confounders such as smoking, diet, and asbestos exposure. The response rate was 81 percent (see Figure 1). Most non-response was the result of our inability to locate the next of kin. Of the responses, 80 percent of the interviews were obtained by mail and 20% via follow-up phone calls; 76 percent were completed by spouses, and 24 percent were completed by some other next of kin. On the average, the next of kin had known the decedents for 39 years (38 for cases, 40 for controls).



10699 Male deaths 1982-83, Central States Teamsters Union
10458 Death certificates found
1288 cases (all lung cancers)
1452 controls (every 6th death, excluding lung cancer, bladder cancer, motor vehicle accidents)
1058 (82%) cases with next-of-kin interviews
1160 (80%) controls with next-of-kin interviews
62 lack adequate* Teamster Union work history
71 lack adequate Teamster Union history
4 lack ever/never smoking data
994 (77%) cases available for analysis using Teamster Union work history
1086 (75%) controls available for analysis using Teamster Union work history
122 lack adequate* next-of-kin work history
128 lack adequate next-of-kin work history
872 (68%) cases available for analysis using next-of-kin work history
957 (66%) controls available for analysis using next-of-kin work history
*Adequate Teamster work history required information on occupation and employer for each job, as well as dates (in years). Adequate next-of-kin work history required information on occupation and on duration of occupation.

FIGURE 1—Cases and Controls Use in Study of Lung Cancer and Truck Driving in the Teamsters Union

Men were then classified into the job category in which they had worked the longest (diesel truck driver, gasoline truck driver, driver of both types of trucks, truck mechanic, and dock worker), according to 1980 US Census occupation and industry codes.[5] Those who had never worked in any of these job categories were classified either as non-exposed, or as men who had held other jobs with potential diesel exposure (see Appendix A). Approximately 12 percent of the study subjects could not be classified into a principal job category because of missing data (e.g., the number of years worked in specific jobs was unknown to next of kin).

A second work history file was created based on the Teamster Union pension application which listed all teamster

jobs, as reported by the subject. Each job listed occupation, employer, and dates of employment. Both applicants and Teamster Union staff spent considerable effort to ensure the accuracy of these pension applications.

For the Teamster Union data, each job for each individual was assigned a three-digit US Census code (see Appendix A) for occupation and industry[5] (the latter obtained from commercial listings of employers which included type of industry). The four principal job occupations based on Teamster Union records were long-haul drivers, short-haul or city drivers, truck mechanics, and dock workers (see Appendix A). The Teamster Union work history did not provide information on whether men drove diesel or gasoline trucks. Men were again categorized according to the job category in which they had worked the longest. Most men had worked in only one exposed job category.

Diesel trucks were gradually introduced into the trucking fleet in the 1950s and 1960s in most of the country (before 1950s in Western states). Diesel trucks formed the majority of heavy duty truck sales for the first time in 1961.[6] However, many trucking companies (where most study subjects worked) had completed most of the dieselization of their fleets by 1960, while independent drivers and nontrucking firms may have obtained diesel trucks later (personal communication from companies in NIOSH/NCI industrial hygiene survey). We have chosen 1960 as the date used in our analysis, but we also report results using 1965 as the date for presumed dieselization.

Case-Control Analyses

The number of cases and controls available for analysis is shown in Figure 1. The method of analysis was unconditional logistic regression.[7] A series of dummy (0/1) variables was used to estimate the risk of a number of different job categories in relation to the same nonexposed group (see Appendix B).

All data on covariates, such as smoking and diet, were taken from the next-of-kin interview, while work history data were taken either from the Teamster Union pension applications or from next-of-kin interviews. Separate analyses were conducted for each type of work history data. Analyses considered employment (usual versus never) in a principal job category, as well as the number of years worked in that job. In some analyses using the Teamster Union work histories, only employment after 1959 (or 1964) was considered.

Details on covariate selection for inclusion in the model can be found in Appendix B. In summary, the only covariates that were included in the final model were age (five categories), smoking (six categories), asbestos (dichotomous), and a dichotomous variable for having held other jobs with potential diesel exposure. The fit of this basic model and four continuous exposure variables from the Teamster Union work history was evaluated via the method described by Lemeshow and Hosmer.[8] The chi square resulting from this test was 18.0, with 18 degrees of freedom ($p = .46$), indicating a good fit of the model.

Results

Table 1 shows the number of men and the average duration of employment in the different job categories. Table 2 shows the results of analyses when exposure was considered as a dichotomous variable (i.e., main job versus nonexposed), based on Teamster Union and on next-of-kin work history. No single job category had a highly elevated risk compared to non-exposed men, although most were somewhat elevated.

We further analyzed the Teamster Union work history data by estimating risk by duration of employment as a categorical variable (Table 3). When no cutoff date for employment was used, there was little indication of any trend of increasing risk with increasing duration of employment for any of the job categories. When only employment after 1959 was considered, both long-haul (test for trend, $p = .04$) and short-haul drivers (test for trend, $p = .22$) showed an increase in risk with increased years of exposure; truck mechanics showed no increase in risk with increased years of exposure; truck mechanics showed no increase in risk with time. If 1964 was used for a cutoff date instead of 1959, long-haul drivers continued to show a significant positive trend ($p = .04$), and the highest duration category (13+ years) had an odds ratio of 1.64 (95% CI: 1.05, 2.57). Short-haul drivers, however, no longer showed a positive trend. If duration of employment was used as a continuous variable, significant positive trends

TABLE 1—Number of Men and Average Years Worked in Different Job Categories by Case-Control Status, from Teamster Union Work History and Next-of-Kin Data

Teamster Union Data	Number Cases	Number Controls	Average Years in Job Cases	Average Years in Job Controls
Overall	994	1085	na	na
Long-haul truck driving	609	604	24.2	24.0
City truck driving	121	134	23.4	24.5
Truck mechanic	50	37	22.3	23.3
Dock worker	70	92	23.1	23.3
Other potentially exposed jobs	99	143	na	na
No potential for diesel exposure	45	75	na	na
Next-of-kin data				
Overall	994	1085	na	na
Primarily diesel truck driver	176	155	29.6	27.6
Primarily gasoline truck driver	245	309	29.0	29.7
Drove both types of truck	248	246	31.2	31.2
Diesel truck mechanic	43	41	32.4	32.3
Dock worker	28	40	25.4	25.1
Other potentially exposed jobs	87	128	na	na
No potential for diesel exposure	45	75	na	na
Missing required data	122		na	na

TABLE 2—Odds Ratios for Exposure Considered as Main Job (ever vs never)

Job category	Odds ratio* (95% CI)
Teamster Data	
Long haul driver	1.27 (.83–1.93)
Short haul driver	1.31 (.81–2.11)
Truck mechanic	1.69 (.92–3.09)
Dock worker	0.92 (.55–1.55)
Other potentially diesel exposed	1.44 (.88–2.39)
Next-of-kin data	
Truck driver, primarily diesel truck	1.42 (.89–2.26)
Truck driver, primarily gasoline truck	1.22 (.79–1.88)
Truck driver, both types of truck	1.25 (.81–1.95)
Truck mechanic (diesel)	1.35 (.74–2.47)
Dock worker	0.93 (.49–1.78)
Other potentially diesel exposed	1.54 (.93–2.15)

*Adjusted for age, smoking, and asbestos, the reference group is the non-exposed.

were observed both for long-haul drivers and mechanics, but only after 1959.

Similar trend analyses, based on next-of-kin data, are shown in Table 4. None of the job categories showed a significant increasing trend, although men whose main job was driving diesel trucks did show a marginal increase in risk with increasing duration of employment as a truck driver ($p = .12$). For truck drivers who drove 35 years or longer and drove primarily diesel trucks, the odds ratio for lung cancer was 1.89 (95% CI: 1.04, 3.42). If duration was considered as a continuous variable, only the trend for diesel truck drivers approached significance ($p = .09$).

Using either the Teamster Union work history or that supplied by next of kin, there were no significant interactions between age and exposure, or smoking and exposure. It did not appear that excess risks were confined to any specific category of smokers or non-smokers. The results for lagged analyses (discounting any exposure in the five years preceding death) were similar to the analyses with no lag.

Concordance between Teamster and next-of-kin job categories could not be easily evaluated because job categories were defined differently in each data set (e.g., diesel truck drivers based on next of kin, long-haul drivers based on Teamster Union data). Discrepancies between next-of-kin and Teamster Union work history could occur because next of kin were reporting lifetime work history, while the Teamster records only covered Teamster years. However, 90 percent of men identified by next of kin as primarily diesel truck drivers were long-haul drivers by Teamster Union data, and the corresponding proportions were 82 percent for mechanics and 81 percent for dock workers.

Discussion

The Teamsters Union keeps very thorough records regarding their members, which have not yet been fully utilized by epidemiologists. We were able to study Teamster pensioners using data on their vital status and work history which had been collected by the Union's Pension Fund. It is worth noting that the Union, jointly with employers, has created a Health and Welfare Fund which might be used for studying morbidity.

We observed positive trends in lung cancer risk with duration of employment for long-haul truck drivers after either 1959 or 1964 (Teamster work history), and for truck drivers who drove primarily diesel trucks (next-of-kin work

TABLE 3—Odds Ratios According to Length of Employment for Long-haul Truck Drivers, Short-haul Truck Drivers, and Truck Mechanics

Job Category	Length of Employment (years)	Odds Ratio (95% CI)*	Cases	Controls
No Cutoff Date				
Long-haul driver	1–21	1.25 (.78, 1.97)	205	218
	22–27	1.12 (.72, 1.77)	199	195
	28 or more	1.47 (.94, 2.31)	199	195
Short-haul driver	1–21	1.52 (.86, 2.71)	52	52
	22–27	1.73 (.92, 3.25)	40	34
	28 or more	0.83 (.45, 1.56)	29	57
Truck mechanic	1–21	2.23 (.97, 5.17)	22	13
	22–27	1.20 (.53, 2.72)	17	17
	28 or more	1.88 (.66, 5.35)	11	8
*Exposure after 1959***				
Long-haul driver	1–11	1.08 (.68, 1.70)	162	230
	12–17	1.41 (.90, 2.21)	228	203
	18 or more	***1.55 (.97, 2.47)	213	171
Short-haul driver	1–11	1.11 (.61, 2.03)	36	58
	12–17	1.15 (.63, 2.43)	37	45
	18 or more	1.79 (.94, 3.42)	40	31
Truck mechanic	1–11	1.83 (.80, 4.19)	19	16
	12–17	2.08 (.78, 5.52)	15	8
	18 or more	1.50 (.59,3.40)	16	13

*These data reflect two analyses, with employment restricted to after 1959 or without such a restriction. Each analysis included all the above exposure variables. Odds ratios were also adjusted for age, smoking, and asbestos. Variables for work as a dock worker or in other potentially diesel-exposed jobs were also included in the model. For all comparisons, the non-exposed were those who had never worked in principal jobs categories nor in any other job potentially exposed to diesel exhaust.

**For the 1959 cutoff, we have used different cutpoints, because the maximum possible length of employment in a given job category is 23 years (1960–83). Cutpoints were chosen a priori by dividing long-haul drivers into three groups of approximately equal size. See text for results using 1964 cutoff.

***The linear trend in odds ratios for long-haul drivers was significant ($p = .04$). The coefficient was 0.027, which increased to .037 when exposure was defined after 1964.

SOURCE: Teamster Union Work History.

TABLE 4—Odds Ratios According to Length of Employment for Men as a Truck Driver or Mechanic for Men Whose Main Job Was Diesel Truck Driver, Gasoline Truck Driver, Driver of both Gasoline and Diesel Trucks, or Truck Mechanic

Main Job Category	Years of Employment* (years)	Odds Ratio (95% CI)**	Cases	Controls
Diesel truck driver	1–24	1.27 (.70, 2.27)	48	52
	25–34	1.26 (.74, 2.16)	72	67
	35 or more	1.89 (1.04, 3.42)	56	36
Gasoline truck driver	1–24	1.24 (.74, 2.16)	72	87
	25–34	1.10 (.67, 1.80)	87	112
	35 or more	1.34 (.81, 2.22)	86	111
Drove both truck types	1–24	1.27 (.71, 2.26)	50	51
	25–34	1.15 (.70, 1.90)	95	100
	35 or more	1.34 (.81, 2.20)	102	95
Truck mechanic	1–24	1.69 (.61, 4.67)	11	9
	25–34	1.39 (.63, 3.07)	20	16
	35 or more	1.09 (.44, 2.66)	12	16

*Years of employment as a truck driver does not necessarily signify years of employment driving a particular type of truck.
**All the above exposure variables were included in the model together. In addition, odds ratios were adjusted for age, smoking, and asbestos. Dock workers and men in other potentially exposed jobs were also included in model. For all comparisons, the non-exposed were those who had never worked in principal job categories nor in any other jobs potentially exposed to diesel exhaust.
SOURCE: Next-of-Kin Data

history). These findings suggest that there may be a real increase in risk with increased employment driving a long-haul or diesel truck.

Mechanics showed marginal elevated risks of lung cancer, especially based on Teamster work history. Preliminary sampling results from NIOSH/NCI surveys indicate that mechanics are likely to have been exposed to relatively high levels of diesel exhaust, especially in winter. However, the risk for mechanics did not appear to increase consistently with duration of employment. Also, there is evidence in the literature that mechanics have been exposed to low levels of asbestos in the course of working on brakes.[9] While we included data from next of kin on asbestos exposure in the model, the data on asbestos may have been inadequate to control for confounding.

Dock workers showed a slight deficit in risk. It is possible that dock workers have had less diesel exposure than truck drivers and mechanics. Dock workers frequently unloaded trailers disconnected from the cabs with engines in open air terminals. Short-haul drivers in the Teamster data, but not gasoline drivers (next of kin data), showed some evidence of increased risk.

The principal limitation in this study is the lack of exposure data indicating level of diesel exhaust for the different job categories studied. Such data would enable us to draw firmer conclusions with respect to the role of diesel exhaust, rather than employment in presumably diesel-exposed jobs. Unfortunately, little data exist on historical levels of diesel exhaust in the trucking industry.

Other limitations include: 1) possible misclassification of smoking habits by next of kin, 2) misclassification of exposure by next of kin, 3) a relatively small non-exposed group (n = 120) which by chance might have had a low lung cancer risk, and 4) lack of sufficient latency (time since first exposure) to observe a lung cancer excess. On the other hand, next-of-kin data on smoking have been shown to be reasonably accurate[10], non-differential misclassification of exposure (between cases and controls) would only bias our findings toward the null hypothesis of no association, and the trends of increased risk with increased duration of employment in certain jobs would persist even if the non-exposed group had had a higher lung cancer risk. Finally, the lack of potential latency would also make any positive results more striking.

In view of the above limitations, the results of this study should be considered cautiously. However, other recent findings support our results. The study of Boffetta, *et al*,[3] based on data from the American Cancer Society, indicates that truck drivers show an increased risk of lung cancer after correction for smoking (RR = 1.24, 95% CI: 0.93, 1.66), and that this increase is primarily associated with truck drivers with long duration of diesel exposure (self-reported). Other recent data support an increased lung cancer risk due to diesel exposure in general. The Boffetta study cited above showed an increased in lung cancer risk for those with diesel exposure in any occupation (RR = 1.18, 0.97–1.44), and this risk increased with duration. Garshick, *et al*,[4] conducted a case-control study of 1,256 lung cancer cases and matched controls who had died in 1982–83 after railroad work. Industrial hygiene assessments were done to determine which job categories had significant exposure to diesel exhaust. Those men with 20 years or more duration of employment in diesel-exposed jobs after 1959 (date when locomotives were all presumed to be diesel) showed a significant excess risk (odds ratio = 1.41) compared to the non-exposed, after controlling for smoking and asbestos. These positive findings for truck drivers and other diesel-exposed workers lend plausibility to our own results.

ACKNOWLEDGMENTS

The NIOSH clerical staff, led in this study by Pauline Bishak, and the Central States Teamsters Pension Fund staff (particularly Alan Levy, Mary Balint, Viola Baba, and Mark Felke) performed invaluable service in collecting the raw data for this study. A preliminary version of this paper was presented at the American Public Health Association conference in Chicago, October 25, 1989.

APPENDIX A

1980 Census[5] Occupation and Industry Codes Used in Defining Job Categories in Teamster Union Work Histories

Job category	Occupation Codes	Industry Codes
Long-haul driver	804 (truck driver, heavy)	any
City driver	805 (truck driver, light)	any
	806 (driver/sales for bakeries dairies, cleaners, or beverage company	111, 101. 771, 120, any if occupation is sales or route driver
Truck mechanic	507 (truck mechanic)	410 (trucking)
Dock worker	343 (checker)	410
	359, 363 (dispatcher)	410
	364 (shipping clerk)	410
	365 (stock clerk)	410
	368 (checker)	410
	843 (dock foreman)	410
	883 (dockman)	410
	856 (forklift operator)	410
	889 (warehouseman)	410
	859 (moving man)	410
Other jobs with potential diesel exposure	all except above jobs in 410 (trucking)	410
	503–517 (other mechanics)	any
	803–859 (other vehicle drivers)	any
	343 (checker)	any except 410
	359, 363 (dispatcher)	any except 410
	364 (shipping clerk)	any except 410
	365 (stock clerk)	any except 410
	368 (checker)	any except 410
	843 (dock foreman)	any except 410
	883 (dockman)	any except 410
	856 (forklift operator)	any except 410
	889 (warehouseman)	any except 410
	859 (moving man)	any except 410
	885 (service station work)	any
	019 (Teamster official)	410

APPENDIX B

Definition of Non-exposed and Selection of Covariates for Inclusion in the Model

The same non-exposed group was used for the analyses based on Teamster Union work history and the analyses based on next-of-kin work history. The non-exposed group was chosen from those who, based on Teamster work history, had never worked as either a long-haul driver, a short-haul driver, a mechanic, a dock worker, or any other potentially diesel-exposed job (Appendix A). Many of these men worked in dairies. Those with no potential diesel exposure via Teamster work history (n = 156) were then further reviewed to exclude anyone with any jobs reported by next of kin which might have had potential diesel exposure (e.g., men who drove trucks prior to joining the Teamsters Union and working in a non-exposed job). The classification of men into the non-exposed group, like all classifications into job categories, was done without any knowledge of case-control status.

Exposure variables and covariates were tested by adding them to a basic model, which included variables for smoking (six categories) and age (five categories). The odds ratios for lung cancer did not increase monotonically with age (using the youngest group as referent), prompting our use of categorical rather than continuous age variables (odds ratios, in reference to age less than 45 years, were 2.86 for ages 45–54, 3.42 for ages 55–64, 3.71 for ages 65–74, and 2.12 for ages greater than 75). Cigarette smoking was categorized into never smoker, current smoker (current at time of death) with unknown amount, current moderate smoker (one pack or less), current heavy smoker (more than one pack), former smoker who quit before 1963, and former smoker who quit 1963–79. The odds ratios for smokers, in reference to never smokers, were 5.64 for current light smokers, 8.85 for current heavy smokers, 4.48 for former smokers who quit in the 20 years before death, and 2.41 for former smokers who quit prior to 20 years before death.

Variables other than exposures, smoking, or age were not included in the model if they did not act as confounders (did not change the estimates of exposure effect), and if they did not interact significantly with the exposure variables. Trends with duration of employment were tested either via inclusion of continuous variables, or via categorization of duration and a test for trend described by Rothman.[11] Cutoff points for categories of duration were chosen a priori, based on dividing long-haul (or diesel when using next-of-kin data) truck drivers into three categories of duration with approximately equal numbers in each. These same cutpoints were then used for the other job categories.

The following variables were neither significant predictors of lung cancer nor acted as confounders: smoking a pipe or cigar, race, state of residence at death, coffee drinking, work in construction, work in shipyards, and driving a truck with a partner who smoked. The frequency of consumption of certain types of vegetables and fruits was of interest because of a possible protective effect of Vitamin A.[12,13] The only significant diet variable was consumption of deep yellow vegetables. The odds ratio for infrequent consumers (one or two times a month or less) of yellow vegetables was 1.38 (1.10–1.76), and for average consumers (one or two times per week) was 1.26 (.98–1.62), both compared to frequent consumers (three or more times per week). However, these variables did not confound the associations under study and were not included in the final model. Asbestos exposure was a significant predictor (odds ratio = 2.80), had some confounding effect on the exposure variables for mechanics, and was retained in the final model.

Nongenetic Influences of Obesity on Other Cardiovascular Disease Risk Factors: An Analysis of Identical Twins

BETH NEWMAN, PHD, JOSEPH V. SELBY, MD, CHARLES P. QUESENBERRY, JR., PHD, MARY-CLAIRE KING, PHD, GARY D. FRIEDMAN, MD, AND RICHARD R. FABSITZ, MA

Abstract: The importance of genetic influences on obesity has been emphasized recently. We conducted matched co-twin analyses of 250 pairs of White, male, monozygotic twins from the National Heart, Lung, and Blood Institute (NHLBI) Twin Study. Entirely in the absence of genetic influences, obesity was significantly associated with systolic and diastolic blood pressures; one-hour, post-load glucose; total, LDL-, and HDL-cholesterol; and triglycerides among these 42–55 year old men. Similar results were obtained in longitudinal analyses of weight change during adulthood (from mean age of 20 to mean age of 48 years) and risk factor status at middle-age. These results indicate that behaviors and environmental exposures that occur later in life are responsible, at least in part, for the associations between adult obesity and cardiovascular disease risk, supporting the appropriateness of weight reduction efforts during adulthood. (*Am J Public Health* 1990; 80:675–678.)

Introduction

Obesity, hypertension, glucose intolerance, and high lipid levels tend to cluster in families.[1,2] Obesity is also correlated with these other cardiovascular disease risk factors in individuals.[3,4] The extent to which this clustering is caused by common genetic influences on multiple risk factors or by shared environmental or behavioral factors is unknown. In a previous report,[5] investigators from the National Heart, Lung, and Blood Institute (NHLBI) Twin Study demonstrated that many cardiovascular disease risk factors have genetic determinants. Using another analytic approach with the same data, we sought to determine whether associations exist between obesity and the other cardiovascular disease risk factors independent of genetic influences.

Comparison within genetically identical, monozygotic twin pairs removes all genetic variability.[6] If intrapair differences in cardiovascular disease risk factors are related to intrapair differences in obesity, these associations must be attributable to environmental or behavioral, and therefore potentially alterable, influences. In this paper, we use longitudinal data from a group of White, male, monozygotic twins in a matched-pair analysis to assess the nature of the relationships of obesity and adult weight gain with blood pressure, glucose tolerance, and lipid levels at middle-age.

Methods

Study Subjects

Data collection for the NHLBI Twin Study took place between July 1969 and June 1973 in five locations: Framingham, Massachusetts; Indianapolis, Indiana; and Los Angeles, San Francisco, and Davis, California. Participants were 514 pairs of White male twins who were members of the National Academy of Sciences-National Research Council Twin Panel[7] and who lived in California, New England, or within 200 miles of Indianapolis. All twins were born during the years 1917 through 1927 and served in the US Armed Forces during the period from World War II through the Korean War. Twins were ages 42–55 years at the study examination. In this report, only the 250 monozygotic twin pairs were included.

Data Collection

After an overnight fast, both members of each twin pair received physical examinations on the same day by different physicians. Weight and height were measured in pounds and inches. Each individual's weight and height also were obtained from records of the physical examination prior to military induction (ages 17 to 28). After conversion to kilograms and meters, body mass index (BMI) was calculated as the measure of obesity (weight/height^2). Blood pressure was measured three times using a standard sphygmomanometer: first by a nurse, later twice by a physician. The participant was seated, and both systolic and diastolic (Phase V) blood pressures were recorded. The mean of the two physician readings was used in this report. Blood samples were collected to determine glucose tolerance, plasma cholesterol and triglycerides, and serotypes for assignment of zygosity. A 50-g oral glucose load was given one hour before blood was drawn unless the subject had diabetes and was currently using insulin or oral hypoglycemic agents or had glycosuria of 3+ or greater. Glucose levels were measured at the examination centers using an SMA 12/60 instrument (Technicon Instruments, Tarreytown, NY). Total, HDL-, and LDL-cholesterol[8] and triglyceride[9] levels were determined at three regional laboratories; specimens were exchanged to maintain standardization. Additional details of the recruitment process, response rates, zygosity determination, clinical examination, and questionnaire are available.[5,10]

Statistical Analyses

Matched-pair t-tests and linear regression models were computed using SAS computer programs.[11] Both members of a twin pair were included in both the unmatched and matched analyses. However, unmatched analyses were adjusted to avoid overestimating the statistical significance of parameter estimates due to correlated errors between co-twins.[12] For the matched analyses, regression models incorporated intrapair differences of the dependent and independent variables.

The intrapair difference for each variable was obtained by subtracting the value for one twin from that of the other in each monozygotic twin pair. For analyses of weight change, the value of BMI at the military induction physical examination was subtracted from the value of BMI at the study examination.

Sample sizes varied between 219 and 245 pairs in the different regression analyses because of missing values and specific exclusions of individuals using medications that affect blood pressure, glucose, or lipid levels. Because the distribution of triglycerides was skewed toward higher values, we used the natural log transformation on this variable in all regression analyses.

Results

Means and standard deviations for obesity, weight change, and the other cardiovascular disease risk factors for the twins as individuals are presented in Table 1.

Within monozygotic twin pairs, heavier twins had significantly higher levels of systolic and diastolic blood pressures, glucose (one-hour, post-load), total cholesterol, LDL-cholesterol, and triglycerides and lower levels of HDL-cholesterol than their genetically identical, lighter-weight brothers (Table 2). Regression coefficients measuring the association of obesity with each risk factor are indicated in Table 3. Examination BMI was significantly associated with all the cardiovascular disease risk factors in the unmatched analyses, independently of age. Matched-pair regression analyses revealed even stronger, significant, cross-sectional relationships between BMI and the cardiovascular disease risk factors. Only the regression coefficient for HDL-cholesterol was somewhat reduced.

Obesity was then partitioned into two variables—BMI at military induction (average age 20 years), and change in BMI during the 20 to 34 years between the induction and study examinations. The independent influences of the two obesity parameters on the other cardiovascular disease risk factors are indicated in Table 4. In both the unmatched and matched analyses, weight gain during adulthood was significantly associated with all the cardiovascular disease risk factors measured. In addition, induction BMI was independently and significantly related to systolic and diastolic blood pressures, total cholesterol, and triglycerides in the matched analyses. The negative regression coefficient between change in BMI and HDL-cholesterol was the only coefficient smaller in the matched analysis than in the unmatched analysis; the inverse relationship between induction BMI and HDL-cholesterol in the unmatched analysis was reduced and no longer statistically significant in the matched analysis. The proportion of nongenetic variance explained by both measures of obesity in the matched analyses ranged from 4 percent for HDL-cholesterol to 10 percent for total cholesterol, 11 percent for systolic blood pressure, and 13 percent for diastolic blood pressure and triglycerides.

TABLE 1—Obesity Measures at Military Induction and at Study Examination and Cardiovascular Disease Risk Factors at Study Examination (1969–73) in a Sample of White, Male, Monozygotic Twins

Variables	Number of Individuals	Mean ± Standard Deviation
Body mass index (kg/m²)		
at military induction	499	21.9 ± 2.4
at study examination	499	25.7 ± 3.2
change between induction and examination	498	3.8 ± 2.9
Age at study examination (years)	500	47.8 ± 3.1
Systolic blood pressure (mmHg)	439	127.0 ± 16.3
Diastolic blood pressure (mmHg)	439	81.3 ± 10.2
One-hour, post-load glucose (mg/dl)	465	162.6 ± 51.9
Total cholesterol (mg/dl)	491	219.7 ± 35.0
HDL-cholesterol (mg/dl)	486	44.2 ± 12.8
LDL-cholesterol (mg/dl)	485	143.5 ± 33.5
Triglycerides (mg/dl)	490	136.1 ± 89.2

TABLE 2—Mean Levels of Cardiovascular Disease Risk Factors at Ages 42–55 Years Comparing Heavier and Lighter Brothers within Monozygotic Twin Pairs

Variables	Heavier Twin	Lighter Twin	Mean Intrapair Difference (95% CI)
Body mass index (kg/m²)	26.6	24.8	1.8 (1.6, 2.0)
Systolic blood pressure (mmHg)	129.6	124.5	5.1 (3.1, 7.1)
Diastolic blood pressure (mmHg)	82.7	80.0	2.7 (1.4, 3.9)
One-hour, post-load glucose (mg/dl)*	161.7	156.0	5.6 (0.3, 11.2)
Total cholesterol (mg/dl)*	222.6	217.1	5.5 (1.9, 9.1)
HDL-cholesterol (mg/dl)*	43.1	45.3	−2.2 (−3.5, −1.0)
LDL-cholesterol (mg/dl)*	145.7	141.6	4.2 (0.8, 7.5)
Triglycerides (mg/dl)*	147.6	124.9	22.7 (12.5, 33.0)

*Conversion factor to SI Units in mmol/L:
Glucose—0.05551
Cholesterol (total, HDL, LDL)—0.02586
Triglycerides—0.01129

TABLE 3—Regression Coefficients* (± standard errors) for Cross-sectional Relationships between Body Mass Index (BMI) and other Cardiovascular Disease Risk Factors in Middle-Aged, White, Male Monozygotic Twins

Dependent Variables	Unmatched Analysis	Matched Analysis
Systolic blood pressure	1.47 ± 0.28	2.23 ± 0.43
Diastolic blood pressure	1.06 ± 0.17	1.44 ± 0.26
One-hour, post-load glucose	3.95 ± 0.80	4.79 ± 1.22
Total cholesterol	2.43 ± 0.51	3.88 ± 0.74
HDL-cholesterol	−0.97 ± 0.18	−0.83 ± 0.27
LDL-cholesterol	1.13 ± 0.49	2.37 ± 0.71
Ln triglycerides	0.065 ± 0.008	0.073 ± 0.013

*Coefficients are age-adjusted: age was included in the unmatched regression models, but was not related significantly to any outcome; matched co-twin analyses control for age in that co-twins are perfectly matched on age.

Discussion

In response to the recent emphasis on the importance of genes in influencing adult obesity,[13–15] we used data from identical twins to address the following question: do nongenetic differences in obesity contribute to levels of blood pressure, glucose intolerance, and lipids? The results of our analyses indicate that significant associations exist between obesity and many cardiovascular disease risk factors entirely in the absence of genetic influences. These results were obtained from both cross-sectional analyses of obesity and concurrent risk factor status and longitudinal analyses of change in weight during adulthood and risk factor status during middle-age. Furthermore, because matched-pair analyses also control for any factors that are identical or very similar between co-twins, such as the influences of shared early environment and culture, the observed associations

TABLE 4—Regression Coefficients* (±standard errors) for Longitudinal Relationships between Cardiovascular Disease Risk Factors and Body Mass Index (BMI) from Military Induction to Middle-age in White, Male, Monozygotic Twins

Dependent Variables	Unmatched Analysis		Matched Analysis	
	Change in BMI	Induction BMI	Change in BMI	Induction BMI
Systolic blood pressure	1.66 ± 0.31	1.06 ± 0.39	2.27 ± 0.44	1.93 ± 0.79
Diastolic blood pressure	1.18 ± 0.19	0.79 ± 0.24	1.48 ± 0.26	1.09 ± 0.47
One-hour, post-load glucose	4.60 ± 0.87	2.19 ± 1.21	4.99 ± 1.25	3.22 ± 2.29
Total cholesterol	2.83 ± 0.55	1.33 ± 0.77	3.89 ± 0.76	3.80 ± 1.37
HDL-cholesterol	−0.97 ± 0.20	−0.97 ± 0.28	−0.84 ± 0.27	−0.75 ± 0.50
LDL-cholesterol	1.34 ± 0.54	0.54 ± 0.76	2.35 ± 0.72	2.55 ± 1.33
Ln triglycerides	0.075 ± 0.008	0.041 ± 0.011	0.075 ± 0.013	0.057 ± 0.023

*Coefficients are age-adjusted: age was included in the unmatched regression models, but was not related significantly to any outcome; matched co-twin analyses control for age in that co-twins are perfectly matched on age.

may be attributed more specifically to environmental exposures or personal behaviors of adulthood.

These results do not preclude genetic influences on obesity, blood pressure, glucose tolerance, or lipid levels.[5,16] Nor do they reveal the specific, nongenetic mechanisms underlying the associations of cardiovascular disease risk factors with obesity. Obesity may serve as a marker of an atherogenic lifestyle, or it may contribute directly to the increases in blood pressure, glucose intolerance, and lipid levels through mechanical or biochemical pathways. Regardless of the mechanisms involved, the effects observed here are not pleiotropic effects of genes regulating adult fatness. The generalizability of these findings is supported by the comparability of the twins participating in this study to White men in the general population[17–19] and to participants in similar studies.[20–23]

Weight change during adulthood was generally more important than baseline BMI at military induction in predicting cardiovascular disease risk factor status in the longitudinal analyses. However, for blood pressure, total cholesterol, and triglycerides, BMI in early adulthood also contributed independently to risk factor status in middle-age. When analyses for all cardiovascular disease risk factors were conducted including both examination BMI (middle-age) and induction BMI (early adulthood) in the models, only the examination BMI was statistically significant (data not shown). These results suggest that the attained level of obesity is important in elevating a person's risk for diabetes and cardiovascular disease, although duration of obesity may also play an independent role.

Although the influence of obesity on the other cardiovascular disease risk factors appears to be limited to less than 15 percent of the nongenetic variability of each risk factor, a significant, if moderate, effect of weight gain during adulthood was observed on each risk factor. The average man in our cohort was 69 inches tall and gained 28 pounds between age 20 and age 48. By middle-age, he had higher levels of each of the cardiovascular disease risk factors studied, except for HDL-cholesterol, than men who gained less weight. Associated with his weight gain were excesses of 9.5 mmHg systolic blood pressure, 6.2 mmHg diastolic blood pressure, 21.0 mg/dl glucose (one-hour, post-load), 16.4 mg/dl total cholesterol, 9.8 mg/dl LDL-cholesterol, and a decrease of 3.5 mg/dl HDL-cholesterol. Similarly, his triglyceride level was 40 percent higher than that of men who did not gain weight between military induction and middle-age; this represents roughly a 50 mg/dl excess. These excesses occurred independent of initial BMI and can be attributed solely to nongenetic influences on the basis of the matched co-twin analysis (Table 4). The cumulative impact of similar or larger weight gains on multiple risk factors clearly contributes significantly to an increase in cardiovascular disease risk.

The causes of adult obesity are complex and undoubtedly involve both genetic and nongenetic influences.[24,25] Bouchard, *et al*,[26] have shown that monozygotic twins generally gain similar amounts of weight as a result of similar diets that include excess calories. However, unrelated twin pairs respond very differently to the same diet. This interpair variability is a reflection of gene-environment interaction, where an individual's response depends both on genetic predisposition as well as specific environmental exposure. Moreover, BMI is only a surrogate measure of obesity and may not capture the most relevant aspect related to cardiovascular disease risk. Unfortunately, more detailed measures of total body fat or fat distribution were not available from the induction or 1969–73 study examinations.

Despite the etiologic complexity of adult obesity, and the well-documented difficulty in its control, our findings provide some reason for optimism. They indicate that behaviors and environmental exposures that occur later in life are responsible, in part, for the association between adult obesity and cardiovascular disease risk factor status. They emphasize the importance of attained weight in influencing that risk, thereby suggesting that weight reduction will be effective even at later ages, when most individuals tend to gain weight. Thus, they confirm the clinical impression that weight control and prevention of obesity are likely to be successful in reducing a person's risk of cardiovascular disease and diabetes.

$3 Million Awarded to Public Health Schools

Almost $3 million in fiscal 1990 capitation grant funds were awarded by the Health Resources and Services Administration to 24 schools of public health.

The funds represent general institutional support which a school may expend for any purpose it judges will most effectively advance its educational program.

The grant recipients and the amounts awarded are:

- University of Alabama at Birmingham, $81,448;
- University of California, Berkeley, $172,670;
- Loma Linda University, California, $131,946;
- University of California, Los Angeles, $206,553;
- San Diego State University, California, $72,000;
- Yale University, New Haven, CT, $77,865;

The Differential Effect of Traditional Risk Factors on Infant Birthweight among Blacks and Whites in Chicago

JAMES W. COLLINS, JR., MD, MPH, AND RICHARD J. DAVID, MD

Abstract: We analyzed 103,072 White and Black births in Chicago from the 1982 and 1983 Illinois vital records, using 1980 median family income of mother's census tract as an ecologic variable. Thirty-one percent of Blacks and 4 percent of Whites resided in census tracts with median family incomes ≤$10,000/year. Only 2 percent of Black mothers, compared to 16 percent of White mothers, lived in areas where the median family income was greater than $25,000/year. Among Blacks with incomes ≤$10,000/year, maternal age, education, and marital status had minimal predictive power on the incidence of low birthweight (LBW) infants. Among high-risk mothers in the poorest areas the proportion of LBW infants in Blacks and Whites was less divergent than in higher income areas. Independent of residential area, low-risk Whites had half the occurrence of LBW infants as Blacks. We conclude that the extremes of residential environments show dramatic racial disparity in prevalence, yet the few low-risk Blacks still do less well than low-risk Whites. Traditional risk factors do not completely explain racial differences in neonatal outcome. (*Am J Public Health* 1990; 80:679–681.)

Introduction

Despite the dramatic improvements in perinatal care during the past 30 years, Black infants are twice as likely as White infants to die during their first month of life.[1–3] This is primarily related to the high incidence of low birthweight (<2500 grams) infants among Black mothers.[4–6] Cities such as Washington, DC, Detroit, and Chicago with large Black subpopulations have the highest neonatal mortality rates (NMR) in the country and are in part responsible for the United States' relatively poor international ranking in neonatal survival.[7] The mechanisms underlying this well-documented phenomenon are not well understood.

Low maternal socioeconomic status (SES) worsens pregnancy outcome.[8,9] Black mothers are more likely to be young, unmarried, poorly educated, and receiving welfare support.[8] However, Spurlock, *et al*,[10] found that poor and non-poor Black infants in Kentucky had no significant difference in birthweight distribution. There is limited available information on mothers of high SES, especially among ethnic groups with widespread poverty. Shiono, *et al*,[5] reported that in a middle class community Black mothers still had a high incidence of LBW infants. Similarly, Kleinman and Kessel[11] found that the ratio of low birthweight for Blacks versus Whites was actually higher among college educated mothers than for women who did not complete high school. Another recent study indicated that a 5 percent racial difference in low birthweight persisted independent of maternal residence.[12] Few studies have addressed the possibility that mature, educated, Black mothers who reside in high income communities might be less likely to deliver low birthweight infants.

For these reasons, we utilized Illinois vital records and US census income data to determine the extent to which disparities in traditional risk factors affect racial differences in pregnancy outcome in Chicago. We particularly wanted to learn if low maternal risk status reduces the number of low birthweight Black infants.

Methods

We analyzed all Black and White births in Chicago using a data set created by appending survival data from infant birth-death tapes as previously described[13] and income characteristics of mother's census tract (from 1980 census tapes) to records in the 1982 and 1983 birth files. Because of their strong association with neonatal outcome maternal age, education, and marital status were used as proxies of individual risk status. Median family income of mother's census tract residence was used as the primary proxy for environmental deterioration. Percent of families within each census tract living below the poverty level was used as an additional ecologic variable.

Among Blacks and Whites we calculated the proportion (per 100 live births) of LBW infants by census tract income, maternal age, and education for the entire study population. We stratified the study population by median family income of mother's census tract to examine the Black-White differential in residential environments. Within each grouped income area, we calculated the frequency of individual and ecologic risk variables. To explore the independent association of residential environment and pregnancy outcome, we determined the relation of maternal age, education, marital status, parity, and history of prior infant death to Black and White infant birth weight.

Relative risk with 95% confidence intervals are presented. Confidence limits were estimated by the Taylor Series method.[14]

Results

There were 51,827 Black and 51,245 White births in Chicago during 1982 and 1983. Black neonatal mortality was twice as high as that of Whites (16/1,000 vs 7/1,000) and the LBW proportions were twice as high in Blacks (14 percent vs. 6 percent). Only 2 percent of Black mothers, compared to 16 percent of White mothers, resided in census tracts in which the median family income was greater than $25,000/year. Conversely, 31 percent of Blacks lived in census tracts in which the average household income was less than $10,000/year; only 4 percent of White mothers resided in such impoverished neighborhoods (Figure 1).

The risk of LBW infants among Blacks remained essentially twice as high as that of Whites across all maternal income, education, and age groups. Although the higher

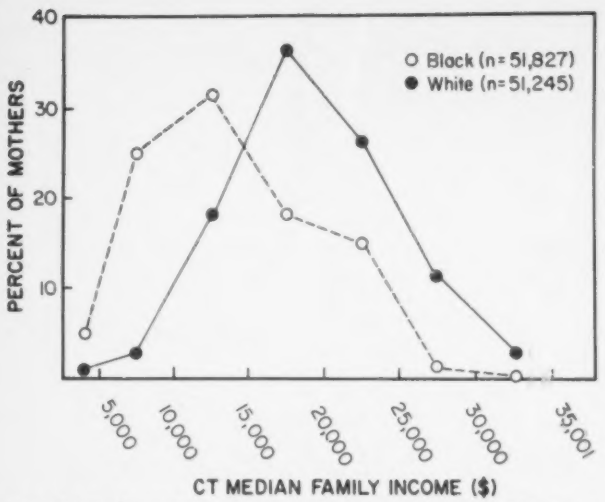

FIGURE 1—Census Tract Median Family Income Distribution of Black and White Mothers

Black risk appeared to be eliminated at very high incomes, the confidence intervals were broad because of the small number of Blacks (N = 200, or 0.4 percent) residing in census tracts with median family income over $40,000/year (Table 1).

Table 2 illustrates the racial distribution of risk factors by census tract income. White mothers were often Hispanic in low-income areas. Among mothers who resided in very low-income census tracts (≤$10,000/year) Blacks were almost 3.5-times as likely as Whites to reside in a census tract where more than one-half of the census tract cohabitants lived below the federally mandated poverty level (RR = 3.47, 95% CI 3.07, 3.92).

The differential effect of race on the LBW rates in low-income areas is apparent with maternal age. Among Black mothers who resided in higher income communities, the high proportion of LBW was minimally reduced and remained twice that of Whites independent of maternal education, age, and marital status (Table 3).

Discussion

We found that high-risk Whites and Blacks had less divergent LBW rates in the poorest areas than in higher income areas while low-risk Whites had half the occurrence of LBW infants as Blacks regardless of the income of the area in which they lived. In Chicago, the percentages of Black and White mothers at the extremes of residential environment are dramatically different. Contrary to Spurlock, *et al*,[10] who reported that poor and non-poor Black infants in Kentucky had no difference in the incidence of LBW, we found that among all mothers, Black and White, low income is associated with a greater risk of low birthweight.

A wider Black-White gap at the upper end of the socioeconomic spectrum has been described in earlier studies such as that by Kleinman and Kessel,[11] but this could have been an artifact of the differences in the economic value of education (the usual proxy for income) between Blacks and Whites in the US. For example, the income disparity between college educated Blacks and Whites is greater than it is for those who did not finish high school.[13] Notwithstanding the limitations of the available grouped income data, our results confirm the results of Kleinman and Kessel and highlight the difficulty in defining a truly low-risk group of Black mothers using traditional risk factors.

Our data suggest that residential environment is an important risk factor that researchers need to take into account when examining the relation between race and neonatal outcome. Residing in a very low-income urban neighborhood is such a strong proxy of low birthweight for Blacks that traditional indicators of favorable outcome (education, age, marital status) fail to identify clearly a low risk subgroup. The intense concentration of extreme poverty combined with the related issues of disintegrating social networks, substance abuse, poor nutrition, smoking, and inadequate prenatal care may produce such a powerful negative force that isolated changes in the classical risk factors do not dramatically reduce the high percentage of low birthweight infants.

Racial differences in intrauterine growth rates exist.[16,17] However, when Wilcox and Russell controlled for Black-White disparities in birthweight distribution, the excess in mortality among Black infants was not eliminated.[17] The study found that a high incidence of small births among Blacks accounted for the majority of Black-White differences in survival.

*Parity was defined as high in third or higher numbered births to women under 25 years of age and fourth or higher numbered births to women 25 to 29 years of age. All other multiparous births were considered to represent low parity.[11]

society are complex and deep-rooted.[8,18] We suspect that the persistently high rate of low birthweight infants among Blacks reflects generations of poverty.[19] While the vital records-based studies can identify factors that affect perinatal outcome, there is a need for studies in greater depth. A limitation of the present study is that even with household income data for each birth we could not truly have "controlled" for Black-White economic differences since income cannot be equated with purchasing power.[20] Moreover, despite treating census tract income as an indicator of the environment within which people live, the lack of homogeneity among mothers of the same grouped income area limits the generalizability of the study.[21] A multidisciplinary approach is needed to better elucidate and remove causes of Black-White differences in neonatal outcome.

In summary, the extremes of residential environment show dramatic racial disparity in prevalence, yet traditional risk factors fail to explain why non-poor Blacks remain at high risk for poor pregnancy outcome. Given that a large percentage of Blacks in this country live at or below the poverty level we need to eliminate economic disparities between the races in addition to providing planned intervention if we hope to see the health gap closed. We suspect that it may require more than one generation of non-poverty and adequate services to see an impact upon infant birthweight.[19]

The Dramatic Increase in the Rate of Low Birthweight in New York City: An Aggregate Time-Series Analysis

THEODORE JOYCE, PHD

Abstract: This paper uses monthly time-series data from 1968 through 1988 to test whether the observed increase in the incidence of low birthweight in New York City represents a reversal of the downward trend that existed prior to 1984. We find that the trend has shifted for both Whites and Blacks. We estimate that between July 1984 and December 1988 there were 3,110 additional low-birthweight births to Blacks and 1,385 additional low-birthweight births to Whites above what would have been expected had the rate of low birthweight not shifted upwards. The incremental costs of treating these infants in their first year of life is estimated at over $22,000,000 in 1986 dollars. (*Am J Public Health* 1990; 80:682–684.)

Introduction

The proportion of low birthweight births among Blacks in New York City has increased dramatically since 1984 and less dramatically among Whites (see Figure 1). This upturn represents a radical reversal of the downward trend in the low birthweight rate that had existed since 1968. Between 1968 and 1984 the average monthly percentage of low-birthweight births among Blacks in New York City fell from 13.9 to 10.1; by 1988, the average monthly rate had risen to 12.9. Given the present rate of increase, the rate of low birthweight among Blacks in 1990 will exceed the rate that existed 22 years earlier. This paper applies several statistical methods to the 21 years of monthly, race-specific data from New York City to measure the trend reversal in the rate of low birthweight since 1984. It also estimates the financial costs of such an increase in the incidence of low birthweight.

Methods

Data

The data on low birthweight are from micro-level vital statistics for New York City. Each year of data has been aggregated by month for Blacks and Whites separately from January 1968 through December 1988 (N=252). The data for Whites contain a large component which is Hispanic because ethnicity was not identified on New York City birth certificates until 1978. Moreover, the proportion of births to White women of Hispanic origin has increased over time. In 1978, for instance, 28 percent of all births in New York City were to women of Hispanic descent and 34 percent of all births were to White non-Hispanic women. By 1987, the Hispanic portion had risen to 30 percent while the White non-Hispanic portion had fallen to 29 percent. The implications of a shift in the ethnic distribution of births among Whites are discussed below.

New York City averaged approximately 100,000 resident live births per annum over the time span under study. The percentage of births to Whites and Blacks has varied between 69 percent White and 29 percent Black in 1970 to 57 percent White and 36 percent Black in 1987. Between 1968 and 1988 there were approximately 6,000 White births and 3,000 Black births per month.

Statistical Methods

Two approaches are used to illustrate the changes that occurred in the incidence of low birthweight in 1984. First, the race-specific rate of low birthweight is regressed on a constant, a linear trend term, a dummy variable that equals zero prior to July 1984 and one thereafter, and an interaction trend term. The interaction term is the product of the linear trend term and the dummy variable. An additional set of 11 dummies is included to control for seasonality. A negative coefficient on the trend term and a positive coefficient on the interaction term would be evidence that the downward trend in the rate of low birthweight prior to July 1984 had turned upwards after that point.[2] The sensitivity of the regression estimates are tested by re-estimating the model with January 1984 and January 1985 as the point at which the trend is assumed to have changed.

Another means of illustrating how the low birthweight series have changed involves the use of Box-Jenkins techniques.[3,4] Specifically, an autoregressive-integrated-moving-average model (ARIMA) is fit to each of the series from January 1968 through July 1984. The fitted model is used to project the rate of low birthweight that would have been observed if the underlying process which generated the observed data between 1968 and 1984 had not been altered. The projected rate of low birthweight is compared with the actual rate in order to approximate the additional number of

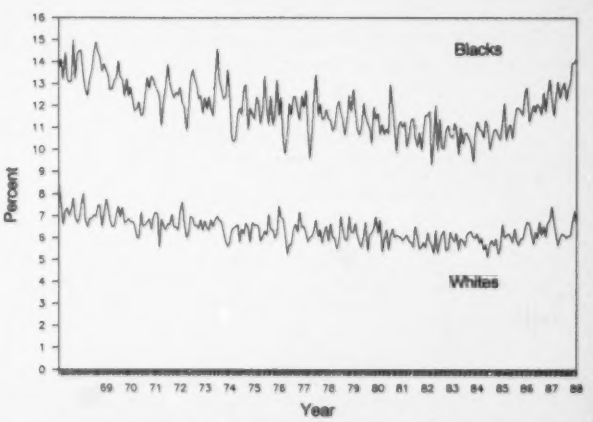

FIGURE 1—Percent of Low-Birthweight Births among Blacks and Whites, New York City, 1968–88

low-birthweight births that have occurred as a result of the shift in the trend. The additional number of low-birthweight births are multiplied by national estimates on the short-term and long-term costs of low birthweight in order to estimate the financial burden of the increase in low birthweight.

Results

Estimates from the linear regression are presented in Table 1. For Whites and Blacks the downward trend in the rate of low birthweight became positive after July 1984 as evidenced by the negative coefficient on the trend term and the positive coefficient on the interaction trend term. The results are insensitive to the switching point of the interaction term from July 1984 to either January 1984 or January 1985 (additional regressions not shown).*

We fit ARIMA models to the low birthweight series based on data from January 1968 through June 1984. To eliminate seasonality, a twelfth-order difference was applied to each series; in the case of Blacks, a first-order difference transformation was also needed to achieve stationarity. Based on the autocorrelation and the partial autocorrelation functions, the low-birthweight series for Blacks can be characterized as a second-order moving average with a first-order seasonal moving average. The series for Whites can be characterized by a first-order seasonal moving average. Estimates of the ARIMA models are presented in Table 2. The Ljung-Box Q-statistic supports the adequacy of the model.

The estimated ARIMA models were used to predict the rate of low birthweight for each race from July 1984 through December 1988. A comparison of the actual rates and the projected rates is presented in Figure 2. What is particularly striking is the growing divergence between the actual and the projected low-birthweight rate among Blacks.

To underscore the magnitude of the change, we multiplied the projected rates of low birthweight from July 1984 through December 1988 by the actual number of live births over the same period. The product yields the number of low-birthweight births that would have been expected based on a 54-month forecast made in July 1984. The difference between the actual number of low-birthweight births and the projected number represents an estimate of the excess number of low-birthweight births above what would have been observed had the rate of low birthweight continued a realization consistent with the previous 16 years. For the entire 54-month period beginning in July 1984, we estimate that there have been 3,110 additional Black low-birthweight births and 1,385 White low-birthweight births.

To assess the financial burden of the additional low-birthweight births, we used cost estimates from the US Congress, Office of Technology Assessment.[5] The figures represent the incremental costs of a low-birthweight birth; that is, the costs above those associated with a normal-weight delivery. The costs are broken down into three categories: initial hospitalization, rehospitalization, and long-term treatments. To simplify matters, we grouped initial hospitalization and rehospitalization under the rubric of short-term costs. Long-term costs refer to expenses beyond the first year of life. The report found that, on average, the short-term costs of a low-birthweight birth ranged from a low of $5,040 to a high of $7,525 in 1986 dollars. If long-term costs were added, the total incremental costs varied from $14,040 to $30,525 per low-birthweight birth.

We focus on the short-term costs since these expenses have already been incurred. For Blacks, the total short-term costs associated with the excess number of low-birthweight births range from a low of $15,674,400 to a high of $23,402,750 in 1986 dollars. For Whites, the comparable costs are between $6,980,400 and $10,422,125.

Discussion

The increase in substance abuse is the most likely explanation for the increase in the incidence of low birthweight. New York City birth certificates reveal that between 1981 and 1987 the number of infants born to drug-abusing mothers rose from 6.7 per 1000 live births to 20.3 per 1000 live births, a tripling of the rate.** The extent of the underreporting is potentially serious, but the point is unlikely to change: the number of infants exposed to drugs has increased precipitously over the last four years. Moreover, there is a growing body of epidemiological evidence which links the use of cocaine during pregnancy to an elevated risk of low birthweight.[6-8] Finally, no other risk factors reported on birth certificates appear to have undergone sufficient change to account for the increased incidence of low birthweight. Annual data show little variation in the percentage of births to women with late or no prenatal care, the percentage of births born out-of-wedlock, and the percentage of births to women on Medicaid.[1]

The increase in the incidence of low birthweight has had relatively little impact on the neonatal mortality rate. Among Black non-Hispanics, for example, the neonatal mortality rate stood at 13.6 in 1983, 11.8 in 1984, 13.6 in 1985, 12.3 is 1986, and 13.4 in 1987.[1] The provisional figure for 1988 is 14.6.*** Among White non-Hispanics, Puerto Ricans, and other Hispanics, the neonatal mortality rate has either fallen slightly or remained essentially unchanged since 1983. The mortality rates imply that many of the additional low-

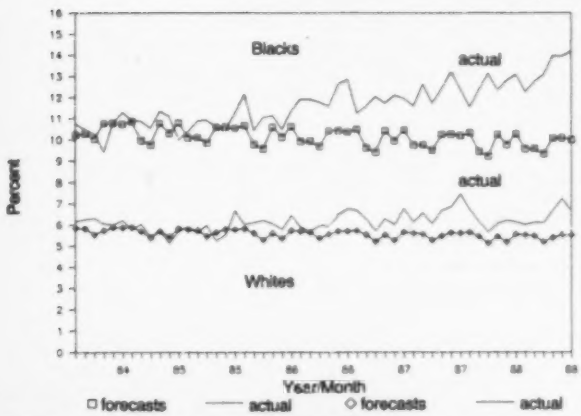

FIGURE 2—Percent of Low-Birthweight Births (forecast vs actual) among Blacks and Whites, New York City, July 1984–December 1988

birthweight infants survive the first month of life. However, the upturn among Blacks in 1988 suggests that the capability of the tertiary care system to manage the increase in low-birthweight births may be limited.

As mentioned above, the proportion of White births to women of Hispanic origin has risen over time. If the rate of low birthweight among Hispanics is higher than that of White non-Hispanic women, then the increase in the incidence of low birthweight among White women may simply reflect the change in the ethnic composition of White births. However, the increase in the proportion of White births to women of Hispanic descent has been dominated by an increase in non-Puerto Rican Hispanics. The incidence of low birthweight and neonatal mortality among this group of Hispanics is almost identical to that of White non-Hispanics.[1] Thus, the growth in the proportion of White births to women of Hispanic origin is not a good explanation for the increased incidence of low birthweight.

The lack of monthly data on substance abuse by pregnant women prevented a more direct test of whether the rise in the proportion of low-birthweight births is associated with the growth in substance abuse. Nevertheless, the increase in the aggregate rate of low birthweight in a city the size of New York is an important, yet troubling finding. At the very least it indicates a deterioration in the health of newborns in New York City. Moreover, anecdotal evidence from the daily media suggests that the use of cocaine, or its derivative crack, among pregnant women is a worsening problem in cities across the United States. If substance abuse is the causal factor behind the unprecedented rise in the incidence of low birthweight in New York City, then one can expect similar increases in low birthweight in other parts of the country. Given the costs of treating low-birthweight children, action taken now may be highly cost-effective.

Secular Change in Birthweight among Southeast Asian Immigrants to the United States

De-Kun Li, MD, MPH, Hanyu Ni, MD, Stephen M. Schwartz, MPH, and Janet R. Daling, PhD

Abstract: We analyzed the Washington State births in 1980–1986 to Southeast Asian parents whose birth place was coded as being outside of the US. The mean birthweight increased from 3188 grams in 1980–81 to 3283 grams in 1986, an annual increment of about 18 grams (95% CI = 11, 25 grams). The prevalence of low birthweight (<2500 grams) decreased from 7.2 percent in 1980–81 to 5.4 percent in 1986, an annual reduction of 6.4 percent (95% CI = 1.3, 11.2 percent). In an analysis of information ascertained from the birth certificate, the change of paternal occupational status (from student to employed) was associated with 27 percent of the reduction in the prevalence of low birthweight, independent of maternal age, infant sex, and prior gravidity. A similar temporal change of birthweight during the same period of time was not observed among infants of US-born Asian mothers. Among the women who had two consecutive births from 1984 to 1986, the improvement of birthweight for the second birth compared to the first birth was much greater in infants born to the Southeast Asian mothers than that to White mothers. Our study suggests that living in the United States after immigration from their native countries has had a positive impact on the birthweight of infants born to Southeast Asian immigrants. (*Am J Public Health* 1990; 80:685–688.)

Introduction

Since the mid 1970s, approximately 800,000 Southeast Asian refugees have immigrated to the United States.[1] At the time of their arrival, the majority of these refugees were of lower socioeconomic status than the general population of the US, and had undergone severe hardships.[2] Health assessment by local and federal agencies revealed several serious problems among this population, including nutritional deprivation, anemia, and psychiatric disorders.[3–7] In addition, it has been reported that they lacked adequate prenatal care and were at high obstetric risk.[8] Since their arrival, however, several programs have been established to help these recent immigrants with financial support, education, and health care.[2] This study attempted to evaluate whether or not the risk of low birthweight has changed over time among Southeast Asian immigrants and, if so, to determine what factors may have accounted for any change observed.

Methods

Washington State contains one of the largest populations of Southeast Asian refugees[2]; the peak wave of the immigrants occurred in the late 1970s and early 1980s.* All births between 1980 and 1986 to Washington State residents (both mother and father) whose race was coded as "other Asian" (i.e., Asian but not Chinese, Japanese, or Filipino) and for whom place of birth was coded as "outside US" were selected from computerized files of Washington State Birth Certificates. We reviewed the original certificates of a random 5 percent sample of the selected births for each year to estimate the proportion of those births to parents who were truly born in Southeast Asia. About 70 percent were born to parents from Southeast Asian countries, primarily Vietnam, Laos, and Cambodia, while the majority of the remainder were born to parents from Korea, India, and the Pacific Islands. The following information on each birth available from the file of birth certificates was used in this study: birthweight, maternal age, marital status, gravidity, parity, sex of infant, the number of prenatal visits, the month of first prenatal visit during pregnancy, method of delivery, pregnancy and labor complications, malformation status, mother's smoking status during the pregnancy (ever vs never, available only for the years 1984–86), number of prior spontaneous and induced abortions, and mother's and father's occupations.

The infants born in 1980 and 1981 were taken as the reference cohort that presumably reflected the situation shortly after the immigrants initially arrived in the United States. Births in 1982 to 1986 among this population thus comprised successive comparison cohorts, assuming that the parents of these infants were those that had been in the United States for progressively greater lengths of time. To evaluate whether or not any changes of birthweight in the study population were part of a general trend among births to all Asian parents in Washington State, we also analyzed the 770 births available during the study period to Washington residents (both parents) whose race was indicated as being a specific Asian ethnic group (i.e., Chinese, Japanese, Filipino) or other Asian, and for whom the place of birth was coded as any one of the 50 US States or the District of Columbia.

Average annual changes in the proportion of low birthweight (<2500 grams) and high birthweight (≥3500) were estimated using logistic regression for dichotomous outcomes,[9] while corresponding changes in mean birthweight were estimated using multiple linear regression for continuous outcome.[10] The odds ratio was used as an approximation of the relative risk when dichotomous outcomes of birthweight were evaluated, i.e., the proportion of low birthweight and high birthweight. Although the proportion of the birthweight equal to or greater than 3500 grams is not a rare event (it occurred in about 20 to 30 percent of births in our study), the discrepancy between the odds ratio and relative risk for this outcome is practically negligible. To estimate the proportion of annual change in birthweight accounted for by specific demographic and obstetric factors, we determined the difference between the estimates of annual change

adjusted and unadjusted for the specific factors and divided this figure by the unadjusted estimates of annual change.

To examine more explicitly whether or not increased duration of residence in the US has influenced the distribution of birthweight among Southeast Asian immigrants, data were also analyzed on those Washington State parents who gave birth to two consecutive children during years 1984–87, and who met the same race and birthplace criteria as described above (data from 1980–83 were not available). Thus, the birthweight of the second child born during this period (not necessarily the second child ever born to each woman) was compared to that of preceding birth. In order to distinguish any secular change of birthweight among Southeast Asian immigrants from that among general population in the Washington State, we also analyzed White women who gave birth to two consecutive children during the period of 1984–87 (there were too few US-born Asian women for similar analyses of this type). The risks of low birthweight for Southeast Asian immigrants compared to American Whites were then calculated separately for each of the two births occurring during the years 1984–87. The change in low birthweight among Southeast Asian immigrants beyond the secular change in the general population in the State was computed by dividing the difference of odds ratio between two consecutive births by the odds ratio minus one for the first birth:

$$\frac{(OR_{\text{second birth}}) - (OR_{\text{first birth}})}{(OR_{\text{first birth}}) - 1}$$

Results

The prevalence of low birthweight (<2500 grams) decreased among Southeast Asian immigrants from 7.2 percent in 1980–81 to 5.4 percent in 1986, a reduction of almost 25 percent (RR = 0.75, 95% CI = 0.53, 1.03) (Table 1). During this same time period, the proportion of birthweight equal to or greater than 3500 grams increased from about 24 percent in 1980–81 to 30 percent in 1986, a 26 percent increment (RR = 1.26, 95% CI = 1.09, 1.45). The mean birthweight increased steadily from 3188 grams in 1980–81 to 3283 grams in 1986 with an average increase of 95 grams (95% CI = 62, 120 grams) during the six-year period (Table 1). A similar secular change of birthweight distribution was not observed among US-born Asian population (data available on request to authors).

The analyses of the data from those subjects with two consecutive births during 1984–87 revealed that the prevalence of low birthweight among Southeast Asian immigrants declined 55 percent (OR = 0.45, 95% CI = 0.23, 0.86) in the second birth compared to the preceding birth. Compared to Whites, there was a 92 percent [(1.05-1.61)/(1.61-1)] reduction, after adjustment for maternal age and parity, in the risk of low birthweight for the second birth compared to the preceding birth among Southeast Asian immigrants beyond the secular change among general population (Table 2).

Based on data available from the birth certificate (see Methods), we compared the temporal changes in factors considered *a priori* to be associated with birthweight to the changes of birthweight during the same period of time (Table 3). There were large increases during the study period in the proportion of women giving birth after age 30 and in the primary cesarean section rate. There was also a 60 percent decrease in the proportion of fathers who listed "student" as their occupation. Aspects of reproductive history, maternal marital status, level of prenatal care, and prevalence of cigarette smoking during pregnancy showed little or no variation between 1980–81 and 1986 although information on smoking during pregnancy was only available for the last three years.

From 1980–81 to 1986, there was a 6.4 percent annual reduction in the prevalence of low birthweight, a 5.8 percent annual increase in the proportion of high birthweight (≥3500 grams), and a 17.7 gram annual increment of mean birthweight among immigrants from Southeast Asia (Table 4). Temporal variation of maternal age, infant sex ratio, and prior gravidity explained between 17 and 28 percent of the secular change in birthweight (depending upon birthweight measure) and, beyond the explanatory power of these trends, the change in paternal student status accounted for an additional 16 to 27 percent of the change in birthweight. Together, maternal age, infant sex, gravidity, and paternal occupational status accounted for between 42 and 55 percent of the change in birthweight among births to immigrants from Southeast Asia, and inclusion of other aspects of obstetrical history, prenatal care, method of delivery, infant malformation status, and demographic characteristics in the models did not confound the above results or explain the remaining unexplained portion of the change in birthweight parameters.

Discussion

There are several limitations in our analyses. Most important, we did not review the more than 7,000 birth certificates to distinguish births to Southeast Asian immigrants from births to parents of other ethnic groups also categorized by Washington State as "other Asian." Our review of a random sample of these certificates indicates that if such a distinction were possible, about 70 percent of the study population would be classified as Southeast Asian in origin. However, our review of the birth certificates also

indicates that the proportion of parents who were born in Southeast Asia did not change appreciably over the study period. Since there is little reason to expect that Asians not born in Southeast Asia who were included in our study population would have experienced any noticeable change in their birthweight distribution, the inclusion of such misclassified births (with respect to race) would only lead to an attenuation of the true trends among births to Southeast Asian immigrants.

Another possible source of misclassification that may have arisen in our study is that calendar year (the independent variable in our analyses) is not a perfect correlate of length of time of residence in the US, since some immigrants from Southeast Asia continued to arrive in Washington State from abroad each year, and some immigrated to the US before 1980. Thus, a proportion of the births to Southeast Asian immigrant parents in later years of the study period might have been to recent immigrants, while a proportion of the births in the earlier years of the study period might have been to parents who had been in the US since the mid-1970s. If the health status of more recent immigrants is better than that of past immigrants, which might be reflected in an improved birthweight outcome of their offsprings, the attribution of change of distribution of birthweight that we observed to the length of residence in the US may be spurious. However, our analysis of consecutive births to the same parents during the latter half of the study period showed a decline in low birthweight among immigrants from Southeast Asia which can not be attributable to misclassification of recency of migration. In addition, there is evidence that the health status of recent Southeast Asian immigrants has not improved (at least compared to earlier immigrants) as measured by the prevalence of hepatitis B surface antigen carriers and TB infection.** We therefore believe that this source of misclassification would also lead to observed trends which are, if anything, diminished in magnitude compared to the actual secular changes.

Information on a major risk factor for low birthweight, maternal cigarette smoking during pregnancy, was only available for the three most recent years of the study period. Nevertheless, the proportion of births to mothers who smoked during pregnancy was very low in these years, and was relatively stable, ranging from 3 percent in 1984 to 2.4 percent in 1986. Thus, we feel that our inability to account for changes in cigarette smoking status over the entire study period is unlikely to have explained our results.

The majority of immigrants from Southeast Asia during this period came from underdeveloped parts of their native countries.[1–3] Some of them had experienced nutritional deprivation, starvation, disease infection, and horrible tortures prior to their arrival in the United States.[2–5] Immigration to the United States and the subsequent improvement of their economic and health status might be expected to have

**Cochran J: Director of Refugee Health Program, Department of Public Health, Massachusetts. (personal communication)

some impact on pregnancy outcomes in this population, particularly birthweight. Our study, conducted over a seven-year period, provides evidence that living in the United States has improved the birthweight distribution of infants born to immigrants from Southeast Asia since the time of initial immigration. Of the information available on the birth certificate, secular changes in maternal age, male sex, prior gravidity, and paternal occupation were all correlated with the increase in birthweight. Of these factors, the change in father's occupational status (from "student" to "employed") is the one which is most likely to reflect the change of the Southeast Asian immigrants' socioeconomic environment, which may include improved nutrition, family security, and better adaptation to a new culture. Further research is needed to identify specific factor(s) that might have contributed to the change of birthweight distribution among this population.

ACKNOWLEDGMENTS

The authors thank the Department of Social and Health Services, Health Data Section, of Washington State for allowing the use of birth certificate data, and John T. Riess of the Department of Public Health, Refugee Health Service of Seattle-King County for providing the information on the number of new arrivals of Southeast Asian immigrants to Seattle-King County by year. This study was presented at the 116th Annual Meeting of American Public Health Association in Boston, Massachusetts, November 14–17, 1988.

NIH Consensus Development Conference on Early Stage Breast Cancer

Treatment of early stage breast cancer is the subject of an upcoming Consensus Development Conference sponsored by the National Institutes of Health (NIH). The conference, scheduled for June 18–21, 1990 in Masur Auditorium of the NIH Clinical Center, is open to the public.

The purpose of the conference is to reach agreement on the treatment of early stage breast cancer. Key issues to be addressed are:

- The roles of mastectomy versus breast conservation,
- Optimal techniques for breast conservation,
- Adjuvant therapy for patients with node negative breast cancer,
- Use of prognostic factors in managing node negative breast cancer,
- Directions for future research.

The conference will bring together specialists in oncology, surgery, clinical trials, and other relevant fields to present current scientific thinking about the diagnosis, management, and prevention of breast cancer. William C. Wood, MD, Chief of Surgical Oncology, Massachusetts General Hospital, will chair the panel, which will produce the draft report and invite comments from the conference participants. Potential Exposure and Health Risks of Infants following Indoor Residential Pesticide Applications

RICHARD A. FENSKE, PHD, MPH, KATHLEEN G. BLACK, MPH, KENNETH P. ELKNER, MS, CHORNG-LI LEE, MS, MARK M. METHNER, MS, AND RALPH SOTO, MS

Abstract: Air and surface chlorpyrifos residues were measured for 24 hours following a 0.5 percent Dursban® broadcast application for fleas inside a residence. Two of the three treated rooms were ventilated following application. Maximum air concentrations were measured 3–7 hours post-application. Peak concentrations in the infant breathing zone were 94 $\mu g/m^3$ in the nonventilated room and 61 $\mu g/m^3$ in the ventilated room, and were substantially higher than concentrations in the sitting adult breathing zone. Concentrations of approximately 30 $\mu g/m^3$ were detected in the infant breathing zone 24 hours post-application. Surface residues available through wipe sampling were 0.7–1.6 $\mu g/cm^2$ of carpet on the day of application and 0.3–0.5 $\mu g/cm^2$ 24 hours post-application. Estimated total absorbed doses for infants were 0.08–0.16 mg/kg on the day of application and 0.04–0.06 mg/kg the day following application, with dermal absorption representing approximately 68 percent of the totals. These doses are 1.2–5.2 times the human No Observable Effect Level (NOEL). Exposures to cholinesterase inhibiting compounds following properly conducted broadcast applications could result in doses at or above the threshold of toxicological response in infants, and should be minimized through appropriate regulatory policy and public education. (*Am J Public Health* 1990; 80:689–693.)

Introduction

The health risks associated with residual pesticides in air and on surfaces in residences have only recently been examined from a public health perspective. The Committee on Urban Pest Management established by the US National Academy of Sciences noted that 5,000 health-related incidents involving pesticides were reported as occurring in homes in the US from 1966 to 1979.[1] Home pesticide applications may pose health risks for occupants, particularly infants and children. A study of 20 adult residents exposed to dichlorvos following crack-and-crevice treatments found a slight decrease in group mean serum cholinesterase, with three residents reporting a feeling of illness 24 hours post-application.[2] Six of 21 children admitted to Arkansas Children's Hospital for organophosphate intoxication were judged to have been exposed following insecticide spraying inside the home.[3] A review of 37 hospitalized pesticide poisonings among infants and children at the Children's Medical Center in Dallas, Texas revealed that five cases were due to pesticide absorption following spraying or fogging inside residences.[4] California State agencies reviewed 44 illness reports in 1984 associated with residential pesticide use,[5] and subsequently conducted a hazard assessment for acute intoxication potential among infants following indoor pesticide treatments.[6] Concern also exists regarding the chronic health effects of children's exposure to pesticides.[7]

Residential monitoring studies have focused primarily on ambient air concentrations of pesticides following several types of applications, including termiticide applications,[8–13] DDVP resin strips hung in households,[14–16] and crack-and-crevice or baseboard treatments.[17–22] Recently the US Environmental Protection Agency initiated a major study of pesticide air concentrations in homes.[23] Limited studies of two additional application methods have been conducted. Broadcast applications,[24,25] involve the hand spraying of an aqueous mixture directly onto target surfaces (e.g., rugs, floors, furniture), while total aerosol release applications (foggers)[26–28] involve activation of a pressurized canister in an unoccupied room, with the pesticide aerosol covering all surfaces (walls, floor, ceiling). Both of these methods produce residues on surfaces to be contacted by occupants. Flea treatment by broadcast application was selected for study here because of the potential for both high air concentrations and substantial dermal exposure. A preliminary risk assessment has been conducted for crawling infants (9–10 months of age).

Methods

Sampling was conducted according to guidelines developed by the Canadian government's Department of Health and Welfare.[29] The study was conducted in three rooms of an unoccupied apartment in New Jersey in June 1987, and extended for 24 hours following application. All rooms were carpeted wall-to-wall with 1.2 cm thick nylon pile. Total surface area treated was 45.27 m^2. No heating or air conditioning systems were in operation during the study. Windows or doors were open in two of the three rooms, while no ventilation occurred in the third room.

Chlorpyrifos application for flea treatment was conducted by a licensed pest control applicator. The formulated product, Dursban® L.O. (EPA Registration No. 464-571), contains 41.5 percent chlorpyrifos (O,O-diethyl O-(3,5,6-trichloro-2-pyridyl) phosphorothioate). The formulation was applied approximately 40 cm above the carpet as a 0.50 percent aqueous spray (40 ml/3.785 L water) with a hand-held fan broadcast nozzle attached to a CO_2 pressurized tank. Applications in the three rooms were identical, covering the entire floor and lasting 5–7 minutes per room.

Air samples were collected in duplicate in each room prior to application and at the following time intervals post-application: 0–0.5 hours, 0.5–1, 1–1.5, 1.5–3, 3–5, 5–7. An additional two-hour sample was collected 24 hours post-application. The samplers were placed in the center of each room mounted 100 cm and 25 cm above the treated surface, approximately 1.5 m apart. Battery-powered porta-

ble air sampling pumps with flow rates of 2 L/min were calibrated with the sampling train in line prior to and following the sampling period. Chlorpyrifos vapors were collected with ORBO-44 tubes (Supelpak 20). Tubes were capped and stored in an ice chest for transport to the laboratory.

Aluminum foil squares (10 cm × 10 cm) were placed in the rooms before treatment to measure residues deposited on the carpet surface. Five squares were collected from each room immediately following application (5 minutes). The wipe procedure was based on the standard method of the US Occupational Safety and Health Administration.[30] Sets of three wipes were collected in each room at eight time intervals post-application: 20, 40, 80, 100, 170, 260, 380 minutes, and 24 hours. All areas to be wiped were marked by disposable cardboard frames with 10 cm × 10 cm cut-out interiors. A new plastic glove was worn for each wipe sample to avoid cross-contamination of samples. The wipe consisted of three strokes across the surface with a 7.5 × 7.5 cm surgical gauze pad sprayed lightly with distilled water. This procedure was repeated with a second gauze pad, changing the wipe orientation 90°. Pads were placed in glass storage jars in an ice chest for transport to the laboratory.

All samples were stored at −20°C until analysis. Granular contents of the Orbo-44 tubes were transferred into serum vials filled with 10.0 ml of pesticide-grade toluene. A subset of the samples were analyzed for breakthrough into the secondary section of the tubes, but such breakthrough was negligible. Capped vials were shaken at high speed (100 cpm) for 5 minutes on a mechanical shaking table, allowed to sit for 30 minutes and the extracts transferred to GC vials for analysis. Both the foil and the pads were extracted in 30 ml of toluene on the shaking table at high speed for 30 minutes and the extracts transferred into GC vials.

Samples were analyzed on a Hewlett Packard 5890A gas chromatograph equipped with an electron capture detector. Heptachlor epoxide was added to all samples as an internal standard. The limit of detection for 1-μl injections was 1 picogram/μl. The limits of detection for the sampling media were as follows: air samples, 83 ng/m^3; foil and gauze samples, 0.6 ng/cm^2. Solvent blanks run with each set of samples had no detectable chlorpyrifos. Fortification/recovery studies were conducted for all sampling media. The mean and standard deviation from these studies were as follows: air samples, 85.3% ±6.0; aluminum foil squares, 98.6% ±2.5; gauze wipes, 84.0% ±10.1. Data have been adjusted on the basis of these recovery values. Two air samples, three foil and three wipe samples were collected in each room prior to application. No background chlorpyrifos levels were detected.

Results

Chlorpyrifos levels on aluminum foil samples collected immediately (5 minutes) following application averaged 13.6 μg/cm^2 (±6.1) and levels in the three rooms were not significantly different. Measured deposition corresponded well with the 13 μg/cm^2 value calculated from label recommendations.

Chlorpyrifos residues available by wipe sampling in the ventilated rooms dropped by more than one-half within 30 minutes, averaging 0.7 μg/cm^2 throughout the remainder of Day 1 and 0.3 μg/cm^2 24 hour post-application (Table 1). Surface residues in the nonventilated room followed the same pattern, but were significantly higher at all time intervals.

Chlorpyrifos vapors measured in the sitting adult breathing zone (100 cm above the carpet) increased over time (Figure 1). While concentrations in the ventilated rooms never exceeded 20 μg/m^3, levels >60 μg/m^3 were measured in the nonventilated room 3–5 hours post-application. The effect of ventilation was further reflected in samples 24 hour post-application: >40 μg/m^3 with no ventilation compared to <10 μg/m^3 with ventilation.

Substantially higher chlorpyrifos concentrations were measured in the infant breathing zone (25 cm above carpet), with ventilation having far less impact (Figure 2). Concentrations reached 94 μg/m^3 5–7 hours post-application in the nonventilated room and exceeded 60 μg/m^3 3–5 hours post-application in the ventilated rooms. After 24 hours an equilibrium concentration in all rooms of approximately 30 μg/m^3 was reached. It thus appears that a vertical concentration gradient developed following the application, with the treated carpet serving as a source of volatilized chlorpyrifos. Open windows provided mixing and dilution of air one meter above the carpet, but had much less effect on concentrations near the floor.

Time-weighted averages for the 24 hour post-application period in the infant breathing zone were 41.2 and 66.8 μg/m^3 for ventilated and nonventilated rooms, respectively, substantially higher than the corresponding values of 12.3 and 45.7 μg/m^3 for the adult breathing zone. All of these concentrations exceeded the National Academy of Sciences (NAS) interim guideline of 10 μg/m^3 for chlorpyrifos in indoor air following termiticide treatments.[31]

A risk assessment was conducted based on the scenario of a 9–10 month old infant playing in a carpeted room beginning at least one hour after a 0.5 percent chlorpyrifos

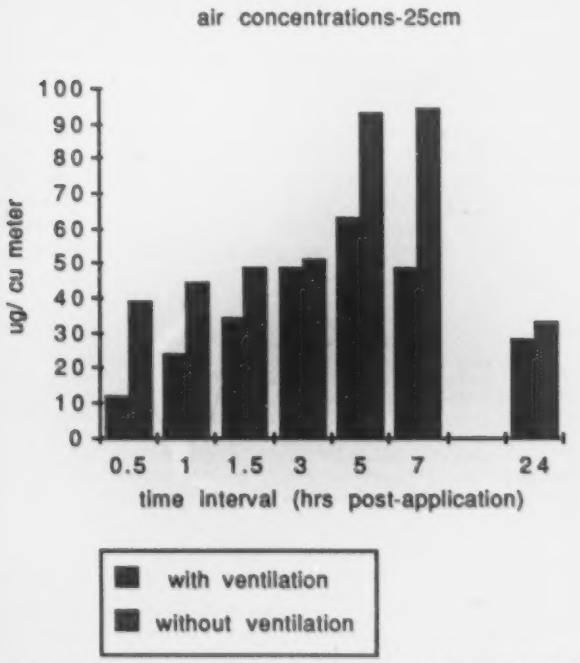

FIGURE 2—Chlorpyrifos Air Concentrations in the Infant Breathing Zone (25 cm)

broadcast application. The following assumptions were employed:

1. Infant weight = 9.0 kg[32]
2. Infant respiratory volume = 2.1 L/min resting (16 hours/day); 6.3 L/min active (8 hours/day)[33]
3. 100% respiratory absorption of chlorpyrifos vapors
4. Total carpet contacted in one day = 2.3 m^2 (25 ft^2)
5. 100% transfer of available residues (wipe samples) to skin
6. 3% dermal absorption of chlorpyrifos[6,34]

Estimated absorbed dermal doses for infants (Table 2) are the product of surface area contacted, available residues (Day 1 and Day 2 in Table 1) and percent absorbed, divided by body weight. The estimated dose in the nonventilated room is 0.120 mg/kg on Day 1, 3.2 times the dose for Day 2. Ventilation reduced the dose estimates approximately two-fold. Estimated absorbed respiratory doses are the product of time-weighted air concentrations, respiratory volume and percent absorbed, divided by body weight. Estimated Day 1 dose with no ventilation is 0.038 mg/kg, more than twice the Day 2 dose. Ventilation reduced the dose on Day 1 by approximately one-third, but had little effect on Day 2 estimates. Total absorbed dose estimates for the day of application are 0.075 and 0.158 mg/kg for ventilated and nonventilated rooms, respectively. Day 2 estimates are approximately 2–3 times lower. Dermal exposure represents on average 68 percent of the total absorbed dose.

Discussion

Chlorpyrifos residues following broadcast application were substantially higher than those reported for other types of residential applications. Total release aerosol applications have produced deposition levels of approximately 2 $\mu g/cm^2$ and maximum air concentrations following ventilation of 14 $\mu g/m^3$.[28] Crack-and-crevice or baseboard applications have resulted in deposition levels of from 1–3 $\mu g/cm^2$,[18,22] and air concentrations of 1–2 $\mu g/m^3$.[20,21] Termiticide applications have produced air concentrations of <1–8.5 $\mu g/m^3$.[11–13] Broadcast applications thus appear to produce deposition levels 5–10 times higher and peak air concentrations approximately one to two orders of magnitude higher than other application procedures. Of further concern is the finding that vapor concentrations increase over the first few hours, peaking 3–7 hours post-application.

The extent to which indoor pesticide applications might produce intoxications among residents is largely unknown. A recent risk assessment calculation of a 2.68 mg/kg absorbed dose for infants in chlorpyrifos-treated residences was based on several conservative assumptions, including complete (100 percent) absorption of chlorpyrifos through the skin.[6] The risk assessment presented here avoids such worst-case assumptions, but includes major uncertainties in the dermal exposure estimates. The rate of transfer of pesticides from treated surfaces to skin and the amount of surface contacted over time are not known. Research has been initiated to adapt fluorescent tracer and video imaging techniques used in occupational exposure studies to address these issues.[35,36] Several factors not included in the dose calculations suggest that chlorpyrifos absorption could be substantially higher. First, a 3 percent dermal absorption estimate may be low. The conventional topical dose for pesticide absorption studies is approximately 40 $\mu g/cm^2$,[37] whereas the average dose applied to the skin in the chlorpyrifos absorption study was >4000 $\mu g/cm^2$.[34] High topical doses result in relatively low percent absorbed values.[38,39] An estimate of the rate of chlorpyrifos penetration through the skin is needed to more accurately estimate absorbed dermal dose. Second, infant skin may be more permeable than the adult skin used to estimate chlorpyrifos absorption. Although the stratum cor-

*Human No Observable Effect Level = 0.03 mg/kg/day

neum of the infant is considered to be fully developed, the permeability of infant skin in humans has not been measured.[39] Studies in infant rats have demonstrated increased percutaneous absorption of chlorpyrifos relative to adults.[40] Third, ingestion from deposits on hands would increase the estimates, since chlorpyrifos is absorbed by the oral route more efficiently than by the dermal route.[34] Finally, skin conditions to which infants may be particularly susceptible (e.g., dryness and rashes) are known to reduce the barrier properties of the skin.[39]

The no observable effect level (NOEL) for chlorpyrifos is based on measurable changes in plasma acetylcholinesterase. The NOEL in humans is 0.03 mg/kg/day.[41] All of the absorbed dose estimates in Table 2 exceed the NOEL, with doses 2.5–5 times the NOEL on Day 1, declining to 1.2–1.8 times on Day 2. The US Environmental Protection Agency has derived a "human reference dose" of 0.003 mg/kg/day for chlorpyrifos by applying a 10-fold safety factor to the human NOEL.[42] The dose estimates in this study exceed the human reference dose by 10–50 times.

NOEL values are commonly employed to determine standards for human safety, but are based on an assumption of continuous exposure (e.g., Acceptable Daily Intakes of pesticide residues in foods). A similar assumption underlies the NAS guideline for indoor air concentrations.[30] Since the potential exposures calculated here would be intermittent, their toxicological significance is difficult to interpret. As yet no short-term toxicological measure analogous to the NOEL is available.

Despite uncertainties in exposure/absorption estimates and toxicological interpretation, the dose values derived in this study raise a public health concern. Broadcast applications and possibly total release aerosol/fogging applications of acutely toxic insecticides may result in dermal and respiratory exposures sufficient to cause measurable toxicological responses in infants. While such exposures are not likely to produce recognizable symptoms of cholinesterase inhibition, the possibility of cases with subclinical effects cannot be ruled out. Confirmation of such exposures would require biological monitoring (e.g., detection of 3,5,6-trichloro-2-pyridinal in the urine for chlorpyrifos).

The potential for exposures greater than those reported here should also be noted. The training of many urban pesticide applicators is minimal and surveillance of application performance is nonexistent in most states. It is not unreasonable to assume that accidents and cases of inadvertent over-application will occur under these circumstances, albeit with low frequency. Furthermore, repeated applications for fleas and other household pests are not uncommon.

Current federal regulatory requirements for indoor pesticide applications are limited to label instructions. The label for broadcast applications of the compound under study here is typical (K. Lunchick, USEPA; personal communication); i.e., the premises should be vacated during application, and humans or pets should not contact treated surfaces until the spray has dried. These instructions are normally communicated by the applicator to occupants as a 1–2 hour reentry period. The finding of elevated air concentrations 3–7 hours post-application and the potential for dermal contact indicate that this reentry period is inappropriate for infants and small children.

Several strategies are available to reduce the risks associated with indoor pesticide applications. First, notification requirements could be established to inform occupants of potential health risks and means for minimizing exposure. Recommendations for broadcast applications of acutely toxic compounds such as chlorpyrifos might include thorough ventilation prior to reentry regardless of seasonal conditions, and well-defined reentry periods beyond 1–2 hours with special warnings regarding contact with treated surfaces by infants and small children. Second, more rigorous training and licensing procedures for applicators and application surveillance programs could be developed. Finally, product registrations could be modified or withdrawn for specific applications if an acceptable level of risk cannot be demonstrated.

ACKNOWLEDGMENTS

A preliminary report of this work was presented at the American Industrial Hygiene Conference, San Francisco, CA, May 15–20, 1988. The authors wish to thank Drs. Molly Coye, Michael Gallo, Philip Landrigan, Thomas Ledoux, and Mark Robson for their review of this manuscript. Special acknowledgment to David Hackathorn and Delmont Eberhart for their early insight into this field of investigation. The technical assistance of William Carey and Western Termite and Pest Control of New Jersey was greatly appreciated. This work was supported by State funds (NJAES Pub. No. D-07124-1-89).

'Late Breaker' Session on Injury Control Invites Abstracts

The Injury Control and Emergency Health Services special primary interest group of the American Public Health Association has announced it will again feature a "late breaker" session during the APHA upcoming 118th annual meeting in New York City. The session will be held on Tuesday, October 2, 8:30 am–10:00 am, and will feature work completed within the last few months—after the deadline for consideration in the regular symposia of the APHA annual meeting.

Abstracts of 250 words or less will be accepted by the Injury Control SPIG until August 15, 1990. Please send the abstract, title of the paper, authors' name, address and telephone number to: Richard Waxweiler, Division of Injury Control, Centers for Disease Control, Mail Stop F-36, Atlanta, GA 30333. Tel: 404/488-4695.

Breastfeeding Patterns in Puerto Rico

Jose E. Becerra, MD, MPH, and Jack C. Smith, MS

Abstract: In the 1950s, Puerto Rico began an active industrialization program. We used data from the 1982 Puerto Rico Fertility and Family Planning Assessment to describe the trend in the incidence of breastfeeding in Puerto Rico over time and to ascertain some of its determinants. From 1946 through 1982, 5,884 infants were born among this statistically representative sample of reproductive-aged women. The proportion of infants who had ever been breastfed was 59 percent for births before 1960 (mean duration = 7.8 months), dropped to 25 percent for infants born from 1970 to 1974 (mean duration = 4.9), and rose to 38 percent for births delivered from 1980 to 1982 (mean duration = 3.4). Prior breastfeeding experience was an important determinant of breastfeeding a newborn. Infants of mothers who had breastfed a previous baby were 7.3 times more likely to be breastfed (95% confidence interval = 6.6, 8.0) compared with infants of mothers who had not previously breastfed. The 38 percent of infants who were breastfed in Puerto Rico in the early 1980s is below the 74 percent to 97 percent reported in Latin America and below the 54 percent reported in the United States for the same period. This study provides baseline data for any future intervention strategies. (*Am J Public Health* 1990; 80:694–697.)

Introduction

A resurgence in the practice of breastfeeding has occurred throughout the world.[1] In the United States the downward trend in breastfeeding practice has been reversed since the late 1970s.[2] Breastfeeding trends vary in less developed countries, and three basic phases of progression have been described.[1]

The traditional phase is characterized by a high proportion of breastfed infants and a long duration of breastfeeding. In the transformation phase, both the proportion of breastfed infants and the duration of breastfeeding show a decrease. The third, or resurgent phase, is characterized by an increase in both the proportion of breastfed infants and the duration of breastfeeding. The patterns of these trends are not uniform in any country; they vary by geography and by the socioeconomic status of different groups.

The relation between the economic development initiated in Puerto Rico in the 1950s and breastfeeding practices among Puerto Ricans has not been studied before. The present study does so, using data from a 1982 survey.

Methods

In 1982, a multipurpose island-wide social, demographic, and maternal/child health study of women ages 15–49 years old living in Puerto Rico was undertaken as a collaborative project involving the University of Puerto Rico School of Public Health, the Puerto Rico Department of Health, and the Centers for Disease Control. The sampling methods have been described in detail elsewhere.[3] The completion rate of the household questionnaire was 91 percent.

A total of 3,175 women were interviewed and, of this number, 2,012 had had at least one live birth. For each live birth reported, mothers were asked: 1) "When your baby was an infant, did you breastfeed him/her?"; 2) "How many months old was s/he when you stopped breastfeeding him/her?"; and 3) "At what age was s/he first given any infant formula, cow's milk, solid foods other than breastmilk on a regular basis?" Of the 2,012 mothers queried, only one mother could not provide a response to any of these questions.

The total number of live births among the women in the sample was 5,884, all delivered between 1946 through 1982. For our analysis, we divided the study period into six birth delivery periods: 1946–59 (N = 709); 1960–64 (N = 924); 1965–69 (N = 1,135); 1970–74 (N = 1,239); 1975–79 (N = 1,207); and 1980–82 (N = 640). We were unable to determine the year of birth for 30 (0.5 percent) infants. Given the blurred distinction between rural and urban areas in Puerto Rico throughout the study period, the place where the delivery occurred (home, private hospital, and public hospital) was used instead of geographical (urban vs rural) correlates.

We used SESSUDAN,[4] a standard errors program, to compute standardized rates from sample survey data and to produce weighed estimates with 95% confidence intervals. We then calculated the proportion of infants who were ever breastfed and the proportion of infants who were exclusively breastfed for at least the first month of life for each birth delivery period stratified by place of delivery (home, private hospital, and private hospital) and by years of maternal education (<12, 12–15, >15) reported at the time of the interview (1982).

We also used the life table analysis program in BMDP[5] to calculate the mean duration of breastfeeding for each birth delivery period and for the three categories of maternal education for births occurring between 1975 and 1982. Infants of mothers still breastfeeding at the time of the interview and infants who had died while still breastfeeding were considered (statistically) censored observations.

We also used SAS[6] to calculate the breastfeeding percent ratio of multiparous mothers with and without previous breastfeeding experience, adjusted for years of maternal education and birth delivery period. In addition, we used the logistic regression program in BMDP[7] to simultaneously determine the strength of association (measured by the odds ratio [OR]) between the infant's breastfeeding status (ever breastfed or not) and maternal age in years (<20, ≥20), place where the mother was raised (continental United States, Puerto Rico), and years of maternal education (<12, 12–15, >15) among primiparas delivering from 1975 to 1982.

Results

In Puerto Rico, the proportion of infants who were ever breastfed was 37.3 percent (95% CI = 34.6, 39.9) for the entire period of 1946 to 1982 (Table 1). This proportion was

(*)the difference between the sample size for total and the summation of cells corresponds to the missing values in each category.

59.4 percent (95% CI = 53.8, 65.0) for births occurring before 1960, dropped to 25.1 percent (95% CI = 21.2, 29.1) for infants born from 1970 to 1974, and rose to 38.3 percent (95% CI = 34.1, 42.4) for births delivered from 1980 to 1982 (Figure 1). The proportion of infants who were exclusively breastfed for at least the first month decreased from 27.4 percent (95% CI = 23.2, 31.3) before 1960 to 4.1 percent (95% CI = 0.0, 7.9) in 1982 (Figure 1).

The mean duration of breastfeeding for all infants throughout the study was 5.6 months (95% CI = 5.2, 5.9). The mean duration of breastfeeding declined consistently from 7.8 months (95% CI = 6.9, 8.6) for births occurring before 1960 to 3.4 months (95% CI = 2.8, 4.0) for births delivered from 1980 to 1982.

Breastfeeding status and place of delivery were related (Figure 2). Before 1975, infants delivered at home or in public hospitals were more likely to be breastfed than were infants

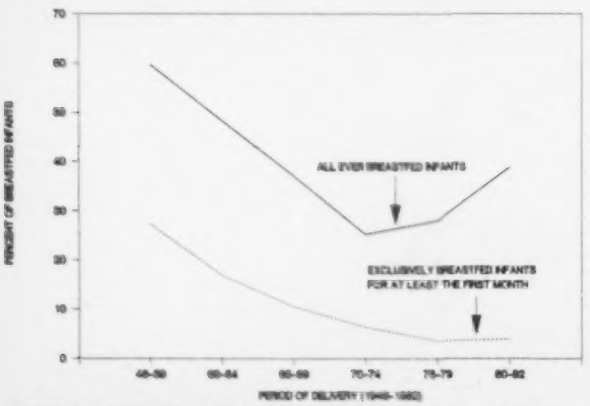

FIGURE 1—Breastfeeding Trends in Puerto Rico, 1946–82: Percent of Infants Breastfed by Birth Delivery Period

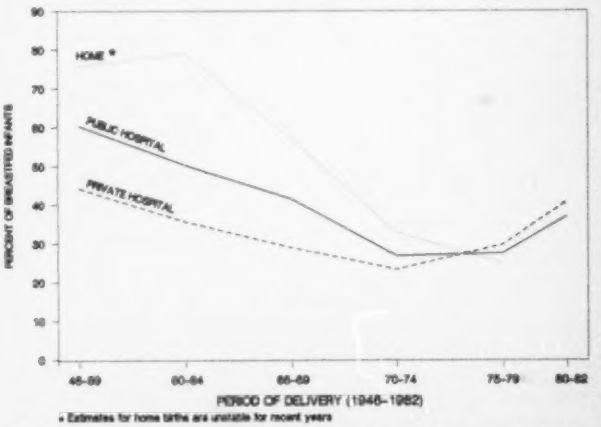

FIGURE 2—Infants Ever Breastfed by Place of Delivery, Puerto Rico, 1946–82

delivered at private hospitals. However, this pattern is reversed after 1975. From 1980 to 1982, 40.6 percent (95% CI = 33.8, 47.5) of infants delivered in private hospitals were ever breastfed, compared with 36.8 percent (95% CI = 30.8, 42.8) of infants delivered in the public sector.

A similarly reversed pattern appears in the practice of breastfeeding after 1975 in relation to maternal education (Figure 3). From 1980 to 1982, 50.0 percent (95% CI = 37.9, 61.6) of infants of mothers with more than 15 years of formal education were ever breastfed, compared with 41.7 percent (95% CI = 36.4, 47.1) for infants of mothers with 12–15 years of education, and 31.4 percent (95% CI = 25.1, 37.8) for infants of mothers with fewer than 12 years of education. However, multiparous mothers with fewer than 12 years of education did not show the same pattern as their primiparous counterparts in recent years (Table 1). From 1980–82, primiparous mothers showed the strongest correlation between

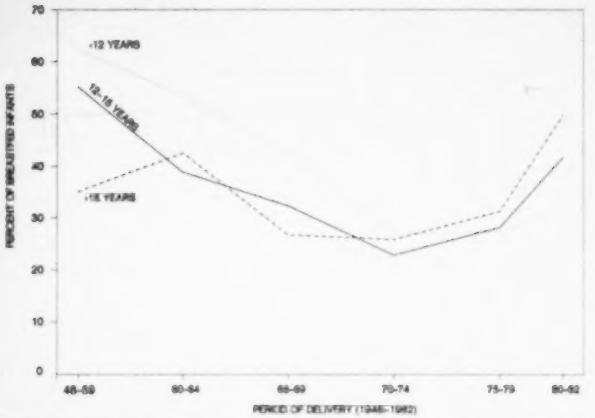

FIGURE 3—Infants Ever Breastfed and Maternal Education at Interview, Puerto Rico, 1946–82

education and breastfeeding practice and the greatest rise in the proportion of infants ever breastfed (Table 1).

From 1975 to 1982, the mean duration of breastfeeding for infants of mothers with more than 15 years of formal education and delivered after 1975 as 3.2 months (95% CI = 2.4, 4.1); the duration was 3.4 months (95% CI = 2.8, 3.9) for mothers with 12–15 years of education and 4.1 months (95% CI = 3.2, 4.9) for mothers with fewer than 12 years.

On the average, infants of multiparous mothers who had breastfed a previous baby were 7.3 times more likely to be breastfed (95% CI = 6.6, 8.0) than were infants of mothers who had not previously breastfed. This measure of association was adjusted for maternal education and birth delivery period.

The place where the mother had been raised, maternal education, and maternal age were examined among primiparas. From 1975 to 1982, maternal education was the strongest independent correlate of breastfeeding among first live-birth infants. Mothers with 12–15 years of education had OR of 1.8 (95% CI = 1.1, 2.8), and mothers with more than 15 years of formal education had OR of 2.8 (95% CI = 1.5, 5.1) compared with mothers with fewer than 12 years of formal education. These estimates were adjusted for maternal age and place where the mother was raised (this latter as a proxy for cultural identification).

Discussion

In the 1950s, Puerto Rico began an active industrialization program that reduced infant mortality from 114.1 infant deaths per 1,000 live births in 1940 to 44.4 in 1960 and 19.2 in 1980.[8] The life expectancy increased from 46.0 years in 1940 to 69.4 in 1960 and 74.9 in 1980.[8]

Our results document that the traditional phase of high rates of breastfeeding among women who delivered at home or in public hospitals and who were less educated declined in Puerto Rico with the advent of industrialization in the 1950s. By 1980, Puerto Rico was between the transformation and resurgent phases of breastfeeding practice. That is, the upward trend in the proportion of infants who were ever breastfed since 1975 was accompanied by a very low and decreasing proportion of infants who were exclusively breastfed during the first month of life. This trend shows that an increasing proportion of mothers who breastfed are probably using formula supplementation during the first month. However, very few medical indications justify introducing food other than breastmilk to a full-term baby during its first four months of life.[9]

Evidence shows that breastfeeding practice in Puerto Rico lags behind the United States and many Latin American countries. For 1980, 54 percent of infants in the United States had ever been breastfed[10] and, for the same period, 74 percent to 97 percent of all infants in selected Latin American countries had ever been breastfed.[11] In comparison, approximately 40 percent of infants born in Puerto Rico in 1980 had ever been breastfed. For Puerto Ricans living in the northeastern region of the United States, the proportion of infants who were ever breastfed is even lower: 26 percent for the 1980–82 period.*

The average number of months that an infant is breastfed in Puerto Rico is consistently decreasing. As previous research has shown in other populations,[12,13] the lack of adequate familial, social, and professional support, and the insensitive employment environment facing modern, highly educated women discourage mothers from breastfeeding. The downward trend in number of months of breastfeeding parallels the decreasing proportion of infants exclusively breastfed for at least the first month of life.

The association between maternal education and breastfeeding is reversed during the upward trend of breastfeeding after 1975. This reversal is consistent with previously published studies.[2] After 1975, mothers with higher education were more likely to initiate breastfeeding than were mothers with less education, whereas the opposite was true before 1960. This pattern is similar to the association between place of delivery and breastfeeding. It is important to realize that institution of delivery is associated with maternal education and socioeconomic status in Puerto Rico.[3]

Although recall bias could be invoked to explain some of these findings, we find no plausible and consistent hypothesis to support such contention. In addition, the general pattern of our results follows the expected interaction between economic development and breastfeeding practices.

Since 1975, maternal education, probably measuring (in addition to socioeconomic status) health behavior awareness and increased capacity to change health belief systems, is strongly correlated with initiation of breastfeeding among primiparas. This trend is encouraging and should guide policy-makers to carry out interventions that will improve breastfeeding practices on the island. However, the decreasing duration of breastfeeding in recent years as maternal education increases provides grounds for concern. This finding differs with previously published studies[14] on the relationship between maternal education and duration of breastfeeding in recent years.

Previous breastfeeding experience was a very strong predictor of breastfeeding a subsequent infant in our study. This fact underscores the importance of role models for young mothers and the self-sustaining nature of a change in breastfeeding behavior. This finding held true even after we adjusted for maternal education and birth delivery period.

In addition to the well known psychological and biological benefits of breastfeeding for the infant,[15] intervention strategies should also emphasize the maternal benefits of

*Carter O, Ezzati T: Breastfeeding practices among Mexican Americans, Cuban Americans, and Puerto Ricans: HHANES, 1982–84 (Abstract). American Public Health Association 115th Annual Meeting, 1987, New Orleans, LA.

breastfeeding: breastfeeding helps postpartum weight loss,[16] breastfeeding prolongs postpartum amenorrhea,[17] and breastfeeding may exert a protective effect against premenopausal breast cancer.[18,19]

In summary, breastfeeding practice in Puerto Rico in 1982 fell between the transitional and resurgent phases of progression. Although we have documented an upward trend in the proportion of infants who were ever breastfed since 1975, more sensitive indicators of breastfeeding practice, such as the proportion of infants who were exclusively breastfed in the first month and duration of breastfeeding, show disturbing decreasing trends in Puerto Rico.

Nominations Invited for 1990 McAlpin Award in Mental Health Research

The National Mental Health Association (NMHA) is seeking nominations for its 1990 McAlpin Mental Health Research Achievement Award to be presented to a researcher in the field of mental illness. The award honors the memory of William R. McAlpin, Jr., who was devoted to the cause of mental health and the advancement of mental illness research.

Nominations will be considered by a panel of judges for researchers whose work offers significant promise in increasing scientific knowledge in the understanding of one or more of the mental illnesses and meets the highest research standards. Previous distinguished recipients are Donald F. Klein, MD, Columbia University; Floyd Elliott Bloom, MD, Salk Institute Center for Behavioral Neurobiology; Paul Greengard, PhD, Rockefeller University; and William T. Carpenter, Jr., MD Maryland Psychiatric Research Center.

The McAlpin Award will be presented during the Seventh Annual National Scientific Symposium on Mental Health and Mental Illnesses, to be held in Houston, Texas, September 14–15. The recipient will be expected to attend the symposium to accept the award.

Nominations from sponsors (individuals and organizations) must be received no later than July 31, 1990. For complete details on nomination procedures contact the NMHA Executive Office, 1021 Prince Street, Alexandria, VA 22314-2971, (703) 684-7722 for a brochure on the 1990 McAlpin Award.

Dietary Intake of Americans Reporting Adherence to a Low Cholesterol Diet (NHANES II)

GORDON SCHECTMAN, MD, W. PAUL MCKINNEY, MD, JOAN PLEUSS, RD, AND RAYMOND G. HOFFMAN, PHD

Abstract: We studied the dietary intake of persons age 18 and over participating in the 1976–80 National Health and Nutrition Examination Survey (NHANES II). We compared the diets of those on a "low cholesterol" diet (dieters, n = 296) with the diets of individuals not following a special diet (non-dieters, n = 10,052). Dietary intakes were assessed by 24-hour recall and food frequency reports and were adjusted for differences in age, sex, race, education, smoking, and socioeconomic status by multivariate statistical techniques. Dieters consumed 16 percent (99% confidence interval- −24, −9) fewer calories than non-dieters, and had decreased intake of saturated fat by 25 percent (−34, −15) and cholesterol by 21 percent (−32, −10). However, their intake of vitamin A, thiamine, riboflavin, niacin, calcium, and iron were not significantly different from non-dieters and their ascorbic acid intake was 18 percent (1, 36) higher. The nutrient density (nutrient/1000 kcal) among dieters was increased over non-dieters by 35 percent (−3, 72) for vitamin A, 35 percent (1, 70) for thiamine, 30 percent (−4, 65) for riboflavin, 27 percent (9, 44) for niacin, 60 percent (40, 80) for vitamin C, 14 percent for calcium (−5, 32), and 15 percent for iron (6, 25). Compared with non-dieters, dieters consumed 27 percent (9, 45) more poultry and 39 percent (12, 66) more fish, but consumed 30 percent (−44, −16) less eggs and 15 percent (−24, −6) less meat. (*Am J Public Health* 1990; 80:698–703.)

Introduction

Recent evidence has linked reduction of blood cholesterol with reduced incidence of coronary heart disease.[1,2] Dietary intervention effectively lowers blood cholesterol levels[3,4] and therefore the cholesterol lowering diet is currently emphasized as an important public health measure. Recent guidelines established by the National Cholesterol Education Program have defined blood cholesterol values above 200 mg/dl as undesirable due to their association with increased coronary heart disease risk[5]; more than half of all Americans fall into this category.[6] Community programs to educate the public concerning hypercholesterolemia and the importance of a proper diet have recently been established,[7–9] and many individuals now report dietary changes in response to these initiatives.[8] Because efforts to enhance knowledge concerning hypercholesterolemia and diet among the public are still in progress, one may anticipate that more Americans will attempt dietary modification in the near future.

Despite this willingness to change dietary habits, the ability of Americans who adopt a "low cholesterol diet" to make significant dietary modifications is unknown. Compared with the typical American diet, the cholesterol lowering diet recommended by the National Cholesterol Education Program is lower in total fat, saturated fat, and cholesterol. In addition, caloric intake is limited, particularly in overweight individuals.[5] To achieve these goals, foods must be substituted into the diet to replace those which are rich in saturated fat and cholesterol. To modify food intake correctly, the dieter must be aware of the basic principles of the cholesterol lowering diet as well as the nutritional adequacy of potential food substitutions. Otherwise, the modification of food choices may have minimal effect on saturated fat and/or cholesterol intake, or may be made at the expense of the intake of other important nutrients. Subjects recruited for research studies designed to evaluate the efficacy of a short period of dietary intervention have generally shown significant decreases in serum cholesterol levels when the diet was instituted, suggesting that appropriate dietary changes were implemented during the study period.[1–4,10,11] However, individuals participating in these studies were highly selected and were provided with intensive nutrition counseling; therefore, they may not be representative of most Americans who wish to adopt a cholesterol lowering diet.

The purpose of this study was to determine if Americans who adopt a cholesterol lowering diet make dietary modifications that: 1) are in accordance with accepted dietary guidelines, and 2) allow for an adequate supply of other nutrients.

Methods

Data were analyzed from the second National Health and Nutrition Examination Survey (NHANES II), a comprehensive population survey which included a detailed dietary questionnaire from which nutrient intakes were calculated in a sample of over 10,000 adults. The NHANES II sample was selected so that population subgroups of special interest for nutritional assessment were oversampled. Among adults, the oversampled groups included persons over 60 years of age and persons below the poverty level. Sample weights were then computed for each participant so that the total sample closely estimated the noninstitutionalized civilian population. This sample weighting reflects the individual selection probability, adjustments for non-response, and post-stratification adjustments. A complete description of the survey methods has been reported.[12]

Data from NHANES II were acquired from sample persons over several visits. At the initial visit, demographic data (i.e., age, education and financial status, household information, etc.) and some of the medical history were obtained. At the second visit, the remainder of the medical history, dietary recall and food frequency information, and blood for laboratory testing were acquired. Adults ages 18 to 74 who attended this second visit were included in this study. Because not all persons who were willing to undergo the initial visit agreed to participate at the second visit, the potential for bias was introduced if these persons differed significantly from other sample persons. The sample weighting in NHANES II was therefore adjusted to correct for this

problem.[13] This sample weight (the "examined final weight") has been employed for all analyses in this paper.

Nutrient intakes for vitamin A, thiamin, riboflavin, niacin, vitamin A, iron, and calcium were estimated from 24-hour recall interviews. These nutrient values were obtained from the US Department of Agriculture reference handbook[14] or directly from the food manufacturer, and were recorded directly on the NHANES II data tapes following completion of the survey. Vitamin and mineral supplements were not included in the calculation of nutrient intake. If two major meals could not be recalled, or if the respondent refused to cooperate or was uncooperative due to attitude, then the recall data were judged to be unsatisfactory by the interviewer. These unsatisfactory interviews were excluded from the analysis; imputed dietary intakes were not substituted for these unsatisfactory recalls. Three-month food frequency reports provided estimates of consumption of specific food groups (such as skim and whole milk, eggs, meat, fish, poultry, etc.). Responses from food frequency questions were converted into the number of weekly servings; respondents reporting occasional intake of less than one serving weekly were arbitrarily assigned a weekly intake of 1/2 serving. Dietary recall data are presented in Tables 2 through 5; data from the food frequency reports are presented in Table 6.

All participants attending the second visit were asked the question "Are you following a special diet?" If they responded affirmatively, they were then asked a series of questions to define the diet, such as "Is this diet to lose weight?"; "Is this a low salt diet?"; or "Is this a vegetarian diet?" Additional questions asked included whether the diet was prescribed by a health professional and the length of time that the diet had been followed. The complete list of questions asked to describe the diet are provided in the Appendix. Participants who were told by a physician that they had a previous heart attack or "hardening of the arteries" were considered to have a history of coronary artery disease. The poverty index, provided in NHANES II, was used to assess socioeconomic status. This is a measure of financial income adjusted to geographic poverty level for family unit; values of less than 1.0 are below the poverty level.

Because the association of dietary cholesterol with blood cholesterol and coronary heart disease was widely recognized during the period when NHANES II was conducted,[15–23] this study evaluated the dietary patterns of individuals (n = 296) who responded affirmatively to the question "Are you following a low cholesterol diet?" We assumed that individuals following this diet were attempting dietary modification to reduce their blood cholesterol levels and hence their risk of coronary heart disease. Multiple responses to define the diet were permitted in the survey. For example, among subjects stating adherence to a "low cholesterol diet," 55 percent also reported following a "low calorie diet," 68 percent followed a low fat diet, 12 percent followed a "diabetic diet," and 54 percent followed a "low salt diet." Respondents who reported following other diets (i.e., high blood pressure, diabetes) in addition to the "low cholesterol" diet were included in this study.

TABLE 1—Characteristics of Study Participants

	Dieters[a]	Non-dieters[b]
N	296	10052
Age (SD)	50.3(14)	39.9(16)
Sex (% male)	49.7	44.7
Race (% White)	91.2	89.8
BMI[c] (SD)	26.6 (4.8)	24.9 (4.8)
History of CAD (%)	25	3
Smoking (%)	25	38
Poverty Index[d]	2.9 (1.5)	2.7 (1.5)
Grade Level[e]	12.2 (2.8)	12.0 (3.1)

[a]Dieters-Study participants who reported adherence to a low cholesterol diet.
[b]Non-dieters-Study participants who did not report adherence to a specific diet.
[c]Kg/m2.
[d]Poverty Index-financial income adjusted to geographic poverty level for family unit; values of less than 1.0 are below the poverty level.
[e]Grade Level-Highest grade completed.

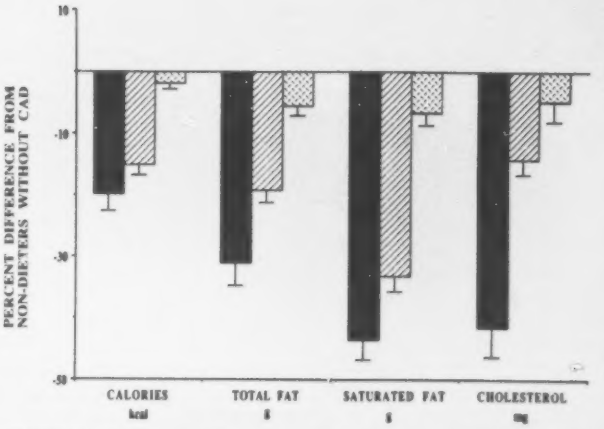

FIGURE 1—The Percent Difference in Caloric, Total Fat, Saturated Fat, and Cholesterol Intake of Dieters with CAD (black bars; N = 72), Dieters without CAD (hatched bars; N = 217), and Non-dieters with CAD (speckled bars; N = 323) compared to Non-dieters without CAD (N = 9681)

A total of 12,501 adults attended the second visit. However, respondents who were following special diets other than a low cholesterol diet (i.e., diabetic, hypertensive, low sodium, low calorie, n = 1,608), who did not have sufficient financial information recorded to compute a poverty index (n = 390), who did not record their level of education (n = 100), or who were judged by the interviewer to have unsatisfactory 24-hour recalls (n = 55) were excluded from the analysis. After these exclusions, 10,348 respondents remained eligible for the study. Those who attended the second visit but were subsequently excluded (n = 2,153) were more likely than included subjects to be male (49.2 vs 38.3 percent), but were otherwise similar to included subjects in percent who were White (89.0 vs 86.4 percent), not following a low cholesterol diet (97.4 vs 96.7 percent), and in their mean age (50.9 vs 45.2 years).

Individuals who were not adhering to any special diet (n = 10,052) were then compared with participants who indicated that they were following the low cholesterol diet (n = 296). In this paper, respondents who reported adherence to the low cholesterol diet are referred to as "dieters"; those subjects not following a diet are referred to as "non-dieters."

Statistical Analysis

Variance estimates were corrected for the complex sample design using the SUPERCARP program.[24] Multiple regression[25] was used to determine the effect of diet status (i.e., dieter compared with non-dieter) on the dietary intake of each nutrient or food group, after adjusting for age, gender, educational level, poverty index, race, and number of cigarettes smoked daily. The body mass index (BMI) was not used

TABLE 2—Intake of Protein, Carbohydrate and Fat among Americans Reporting Adherence to a Low Cholesterol Diet (Dieters) Compared with Americans not Following a Specific Diet (Non-dieters)

Nutrients	Non-Dieters Intake	Dieters Intake	Percent Difference Dieters vs Non-Dieters (99% CI)
Calories (kcal)	2072	1735	−16.3 (−23.7, −8.9)
Protein (g)	80.2	73.7	−8.0 (−15.8, −0.3)
Carbohydrate (g)	225.6	196.5	−12.9 (−21.1, −4.7)

TABLE 5—Mean Vitamin and Mineral Nutrient Density (nutrient/1000 kcal) of Americans Reporting Adherence to a Low Cholesterol Diet (Dieters) Compared with Americans not Following a Specific Diet (Non-dieters)

Nutrient Density (nutrient/1000 kcal)	Non-Dieters Intake	Dieters Intake	Percent Difference Dieters vs Non-Dieters (99% CI)
Vitamin A (IU/1000 kcal)	2618	3790	+34.5 (−3.4, 72.4)
Thiamin (mg/1000 kcal)	0.66	0.89	+35.0 (0.7, 69.7)
Riboflavin (mg/1000 kcal)	0.91	1.18	+30.3 (−4.2, 64.9)
Niacin (mg/1000 kcal)	10.59	13.42	+26.7 (9.1, 44.4)
Ascorbic acid (mg/1000 kcal)	52.7	85.9	+60.1 (39.8, 80.4)
Calcium (mg/1000 kcal)	381	433	+13.8 (−4.9, 32.4)
Iron (mg/1000 kcal)	6.89	7.95	+15.4 (6.2, 24.6)

as a covariate in the analyses presented in this paper because of the potential effect that diet status may have on body weight. However, separate analyses were also performed in which the BMI was included as an additional covariate. All covariates were forced into the model. Dependent variables not approximating a normal distribution were transformed logarithmically; these included saturated fat, milk, poultry, organ meats, vitamins A and C, and the nutrient density of

vitamins A, B_1, B_2, and iron. However, the results of the analysis were not affected by this transformation and, for purposes of clarity and consistency, the data are presented untransformed. The Cook's distance was determined for residuals and found to be less than 0.2, indicating that outliers did not significantly bias the results of the analyses.[26] In Tables 2, 3, 4, and 6, the adjusted mean values for both non-dieters and dieters are given, as well as the percent difference between the dieters and non-dieters. Because of the large number of analyses performed, the 99% CI, rather than the 95% CI, was employed in this paper and is provided in the tables; negative values indicate that the mean intake for dieters is lower than the intake for non-dieters.

Results

Characteristics of dieters are compared with non-dieters in Table 1. Dieters were older, more likely to be female, and have slightly lower BMI than non-dieters, but were similar in poverty index, education level, and race. Dieters were also more likely to have coronary artery disease and less likely to be smokers. The mean duration that the diet had been followed was 147 weeks. A diet prescription was received from a health professional (dietitian, nurse or doctor) by 69 percent of dieters.

Total caloric intake was 16 percent lower (99% CI = −24, −9) in dieters compared with non-dieters, representing a decrease of 340 kcal (Table 2). Although part of this decrease was due to reduced protein and carbohydrate intake among dieters, most of the reduction in total calories was due to a 22 percent (99% CI = −31, −13) decrease in total fat intake. This reduction in total fat intake resulted from lower saturated, monounsaturated, and polyunsaturated fat consumption. Mean cholesterol intake was also reduced in dieters compared with non-dieters (21 percent decrease; 99% CI = −32, −10).

The composition of the diet among dieters also differed compared to non-dieters (Table 3). Dieters had a higher percent of total calories obtained from protein and carbohydrate and a lower proportion of total calories derived from total fat, saturated fat, and monounsaturated fat. The percent of total calories derived from polyunsaturated fat was similar between dieters and non-dieters. Dieters were more likely to meet goal intake levels for the cholesterol lowering diet by restricting total fat to 30 percent of the diet, saturated fat to 10 percent of the diet, and cholesterol intake to 300 mg daily. For dieters, 35.2 percent met this goal for total fat compared with 22.3 percent for non-dieters, while 41.7 percent of dieters and only 23.2 percent of non-dieters met this criteria for saturated fat. For dietary cholesterol, 66.5 percent of dieters, compared with 54.3 percent of non-dieters, achieved the goal level for daily intake.

Because the presence of coronary artery disease (CAD) may also motivate individuals to consume more healthful foods without consciously following a cholesterol lowering diet, the influence of previous CAD on dietary intake was evaluated. Compared to non-dieters without CAD, dieters both with and without a previous history of CAD had decreased caloric, total fat, saturated fat, and cholesterol intake (Figure 1). On the other hand, non-dieters with a history of CAD had caloric, total fat, saturated fat, and cholesterol intake similar to non-dieters without a CAD history.

Despite the decreased caloric intake, dieter vitamin and mineral intake was not significantly reduced compared with non-dieters (Table 4). This finding occurred because dieters selected foods with increased nutrient density (nutrient/1000 kcal). Marked increases in nutrient density were observed in dieters compared with non-dieters for vitamin A, thiamin, riboflavin, ascorbic acid, and niacin (Table 5). Smaller increases in nutrient density for iron and calcium were observed, and the total intake of these minerals in dieters was slightly decreased.

Dieters selected food that conforms to dietary guidelines for a cholesterol lowering diet (Table 6). They consumed 45 percent less whole milk products and 60 percent more skim milk products than non-dieters. Dieters ate 30 percent fewer eggs than non-dieters, and consumed 15 percent less meat. Consumption of poultry and fish were significantly increased compared with non-dieters.

Subsequent analyses were performed using the BMI as an additional covariate. All differences between dieters and non-dieters persisted; inclusion of this variable as a covariate had very little effect on the results for any nutrient, suggesting that the observed differences between groups was not attributable to body mass.

Discussion

Americans reporting adherence to a cholesterol lowering diet had dietary patterns which differed markedly from study participants who were not following any diet. Dieters reduced their intake of calories, total fat, and saturated fat. They consumed less red meat and whole milk and consumed more poultry, fish, and skim milk. Despite these significant differences in diet between dieters and non-dieters, dieters maintained their intake of essential vitamins and minerals by selecting food with increased nutrient density. These dietary trends are in accordance with dietary guidelines designed to reduced blood cholesterol levels. The findings suggest that dieters had sufficient nutritional understanding to make

TABLE 6—Mean Servings from Specific Food Groups Consumed Weekly by Americans Reporting Adherence to a Low Cholesterol Diet (Dieters) Compared with Americans not Following a Specific Diet (Non-dieters)

Food Groups	Non-Dieters Servings/week	Dieters Servings/week	Percent Difference Dieters vs Non-Dieters (99% CI)
Whole milk products	4.55	2.52	−44.7 (−58.6, −30.8)
Skim milk products	2.92	4.66	+59.5 (22.9, 96.1)
Meat	6.53	5.58	−14.6 (−23.3, −5.9)
Organ meats (i.e. liver)	0.38	0.31	−19.2 (−34.6, −3.8)
Poultry	1.34	1.71	+27.0 (8.8, 45.2)
Fish	1.02	1.42	+39.1 (12.4, 65.7)
Eggs	2.68	1.88	−29.7 (−43.5, −15.9)

specific food choices to reduce dietary cholesterol, total fat, and saturated fat without compromising the nutrient intake of their overall diet.

Since NHANES II was conducted from 1976–80, this study reflects the prevailing dietary recommendations during that period. Many advances in the current understanding of the cholesterol lowering effect of specific nutrients have occurred within the past decade.[27] However, the dietary guidelines to lower blood cholesterol levels were formulated in the 1970s and included the recommendations for the reduction of total fat, saturated fat, and dietary cholesterol,[15,16,21–23] similar to those recommended currently.[5] Although the reported dietary intake of dieters was consistent with these recommendations, the extent that knowledge of these guidelines actually influenced and/or motivated dieters to improve their diets cannot be determined from a cross-sectional study of this nature.

It is of interest that 31 percent of the dieters did not receive a diet prescription from a health professional (dietitian, nurse or physician) and decided on their own to follow a cholesterol lowering diet. In fact, they adhered to the cholesterol lowering diet as well as individuals who had received a diet prescription (data not shown). This is important because individuals with desirable (<200 mg/dl) or borderline high blood cholesterol levels (200–239 mg/dl) may be less likely to be referred by a health professional for dietary counseling compared with persons with higher values.[28] Since even individuals with relatively desirable cholesterol levels may benefit from a cholesterol lowering diet, it is reassuring that many Americans can successfully follow this diet even without formal consultation with a dietitian.

This study is limited by the methodological problems associated with estimating dietary intake in cross-sectional studies of free-living populations. Dietary recall of the preceding 24-hour period may not provide an accurate or representative assessment of current nutritional intake for an individual. However, this limitation is lessened when assessing the average intake of a group, since the group mean intake is less sensitive to day-to-day variability.[29] Further error in the data can be introduced during the reporting and recording of food intake, as well as in the analysis of the nutrient content of food.[30] During NHANES II, efforts were made to reduce these sources of error by employing trained interviewers and using a uniform approach to nutrient analysis during the entire survey. Because data from both dieters and non-dieters were acquired using the same methodology, error introduced from these sources would not be likely to bias the results of this study. An additional concern is that questions concerning adherence to a special diet may have biased dietary recall data. For example, individuals who reported adherence to the low cholesterol diet may have underreported ingestion of foods high in cholesterol and saturated fat. However, the questions concerning adherence to specific diets were among hundreds asked of each respondent and were obtained by interviewers who were unaware of the goals of the current study. Therefore, it is unlikely that questions describing the diet biased the reporting of nutrient intake data.

The results of a cross-sectional study alone cannot define the presence of a causal relationship. For example, individuals who naturally prefer diets particularly low in cholesterol and fat may report that they are following a low cholesterol diet. These individuals may not have modified their food intake due to the adoption of a diet. However, this hypothesis is unlikely because dieters, compared with non-dieters, had a much higher prevalence of coronary heart disease, suggesting that they modified their diet in response to this illness. Further, 69 percent of dieters had received the diet prescription from a health professional. Therefore, a more likely explanation for our results is that dietary intake was modified as a consequence of the adoption of the diet.

Diet modification can effectively reduce blood cholesterol levels. Studies specifically designed to evaluate the efficacy of cholesterol lowering diets report cholesterol reductions in the range of 10–15 percent.[11,31–33] Further, the diet is well tolerated.[34] However, perfunctory and routine dietary instruction in patients without proper motivation may have no impact on dietary compliance, weight reduction, or blood cholesterol levels.[35,36] In our study, only subjects who reported that they were following a cholesterol lowering diet were included as dieters. Therefore, individuals prescribed a cholesterol lowering diet but who were unwilling or unable to comply would probably not report adherence to the low cholesterol diet at the time of the survey, and would be excluded from the analysis. Thus, this report is likely to include only respondents who were sufficiently motivated to adopt this diet, and who felt that they were, at least in part, successful. Only 3 percent of the total sample, including only 15 percent of those with coronary heart disease, reporting following the low cholesterol diet. The willingness of the American public to accept this diet will be one important factor determining general compliance and efficacy.

Results from this study indicate that adherents to the cholesterol lowering diet report consumption of foods and nutrients consistent with recommended cholesterol lowering diet guidelines. In addition, the intake of essential vitamins and minerals is not compromised by adherence to this diet. Since the NHANES II survey utilizes a population-based sample, subjects included in the analysis represent a cross-section of the American public. Therefore, this analysis suggests that favorable dietary modifications can be achieved by Americans who choose to follow this diet. Efforts to increase the American public's awareness of the importance of dietary intervention to reduce cholesterol levels and thereby decrease coronary heart disease risk should be emphasized. Once Americans are prepared to adopt the cholesterol lowering diet, these results suggest that healthful dietary modification in accordance with accepted guidelines to reduce blood cholesterol levels is an achievable goal.

APPENDIX

NHANES II Questions Asked to Describe Diet

	Response
Are you on a special diet?	Yes/No
If yes, is this diet to lose weight?	"

Spanish Version of the Nottingham Health Profile: Translation and Preliminary Validity

JORDI ALONSO, MD, JOSEP MARIA ANTO, MD, AND CONCHI MORENO, MD, MPH

Abstract: We report the transfer into Spanish of a multidimensional measure of perceived health originally developed in Great Britain, the Nottingham Health Profile (NHP), and an assessment of the preliminary validity of the version is presented.

Translation of the questionnaire was obtained from experts and from a Spanish monolingual lay group. Construct validity of the version was assessed in two studies: testing relationship of NHP scores to other self-reported measures of health in a general population survey; and comparing NHP scores for a group of frequent users and for a group of non-users of primary health services.

Mean scores of NHP dimensions were higher for people with poorer self-reported health and higher for the frequent health services users than for the non-users.

Findings suggest that the Spanish version of the NHP is culturally equivalent to the original questionnaire, and has a similar level of construct validity. Nevertheless, further research on reliability and on the weighting system is required to establish the equivalence of the Spanish version definitively. (*Am J Public Health* 1990; 80:704–708.)

Introduction

The impetus to produce reliable and valid measures of health has grown dramatically as the need for better evaluation of health services has increased. In the last two decades a number of questionnaires have been designed which measure the physical, mental, and social aspects of health.[1] Although most of these measures have been developed and tested in English-speaking cultures, mainly in the United States, they are widely used in different countries and in non-English-speaking cultures.

The content of health status measures as well as the wording and the form of administration are very dependent on cultural values.[2,3] Transferring a validated instrument to a different culture is an efficient strategy, since developing a new measure is a complex and time-consuming task, requiring much expertise. However, this process should follow a methodology that ensures a similar level of validity, reliability, and cultural meaning for the new version.[4,5] This methodology includes several steps: translation (ensuring conceptual rather than linguistic equivalence), and testing for feasibility, validity, and reliability. Furthermore, measures containing scaled items usually include specific weights for each item, thus making it necessary to validate the weights for the adapted version as well, in order to assure that scores obtained in the original and adapted version have similar meaning.[6,7]

In past work[8] we identified the need for a measure to adequately monitor health status of the population and equity in health services utilization. We have focused our work on adapting a validated measure rather than on developing a new one. We selected the Nottingham Health Profile (NHP), a validated measure of perceived distress developed in Great Britain,[9–12] and previously adapted in Sweden[7] and France.[13]

The NHP is a self-administered questionnaire containing a first part with 38 statements belonging to six dimensions of health (Energy, Pain, Emotional Reactions, Sleep, Social Isolation, and Physical Mobility). The respondent answers "yes" if the statement adequately reflects his/her current status or feeling, or "no," otherwise.[9] British researchers weighted each item in a dimension using Thurstone's paired comparisons method.[14] Part II contains questions on seven areas of daily life.

For transferring the NHP into Spanish, the following strategy was designed: first, a conceptually equivalent translation; second, a preliminary assessment of the validity of the version obtained; and finally develop Spanish weights, contingent upon the establishment of the validity of the unweighted version.

Methods

Translation Process

Ideally, a panel of bilingual people should be used to obtain translations and blind back-translations.[15] Because it was difficult to find a satisfactorily representative panel of bilinguals (same fluency in Spanish as in English, middle/lower socioeconomic class, and experiencing chronic illnesses), a specific methodology for adapting the NHP into Spanish was designed by one of the NHP authors (S. Hunt).[16] After complete explanations by Dr. Hunt, translations of each item were obtained by two of us (JMA and JA). These translations were back-translated into English and discussed again. A list containing translated items and alternative translations was made. Close agreement was reached in most items and they were graded as A "satisfactory agreement" (32 out of 45, 71 percent), B "almost satisfactory but one or two words uncertain" (nine items, 20 percent), and C "doubtful translation" (four items, 9 percent).

In order to overcome these disagreements, a group of 10 Spanish unskilled workers listened to anecdotes that reflected all the items on the questionnaire and described them freely in their own words. These words were added to the list of alternative translations. This list was later presented to the same group in order to point out the expressions they found odd and to select those that would conform to their language usage. The final version included the most popular expressions for items B and C (see Appendix). A pre-test of this version was carried out with a group of cardiology and rheumatology hospital outpatients who were asked to complete the questionnaire and to identify the statements difficult to understand, those that were acceptable, and those easily understood.

Having obtained a Spanish version of the NHP, a translation into Catalan (language of romanic origin similar to Spanish, spoken by some eight million people mainly in the northeastern part of Spain) was also made. Seven Catalan-Spanish bilinguals, who were easy to convene, were used to obtain translations and back-translations and also to decide the exact final wording. The close agreement between both Catalan and Spanish versions led us to include both versions in further studies of the Spanish NHP.

Validation Studies

Achieving conceptual and linguistic equivalence when transferring a questionnaire from one culture to another does not entirely guarantee that the validity of the original version stands in the new culture. Although the method used to translate the NHP into Spanish followed prescribed procedures, the results of this translation were further tested to determine whether it performed in a manner similar to the British NHP.

In order to make an assessment of the validity of the Spanish version of the NHP, construct validity was tested in two studies. First, the relationship of NHP scores to other self-reported measures of health was tested; second, NHP scores for a group of frequent users and for a group of non-users of primary health services were compared.

In the first study, 1,220 participants ages 41 years and over completed the NHP (75 percent Spanish version and 25 percent Catalan version) as part of a random sample health survey of the city of Barcelona.[17] They also provided information about self-rated health (SRH), chronic conditions selected from a list of 34 conditions, chronic limitation of activity due to health problems, and restricted activity in the two weeks before the interview. These variables had been used in previous studies in Spain.[18,19] Social class was assigned to the respondents based on the occupation of the head of the household, following an adaptation[20] of the British Registrar's Social Classification.[21]

In the second study, clinical records of individuals ages 20 and over were sampled systematically from the registry of the Health Center of Barañain (Navarra). Following the criteria of a previous validity study of the British NHP,[11] people were classified as "non-users" if no medical visits were registered in the last six months, and as "frequent users" if three or more visits were made by individuals less than 50 years old, or five or more visits for individuals age 50 and over. As illness was the construct of interest, routine medical examinations were not included. In total, 396 people were considered eligible for the study (195 "non-users" and 201 "frequent users"). They were asked to complete the Spanish version of the NHP and to give information on self-rated health and chronic conditions. Complete responses were obtained from 338 individuals (85.3 percent of the eligible). Following the previous British study,[11] influence of age and sex in the analysis was eliminated by randomly selecting from the respondents a subsample of 276 people containing equal numbers of "non-users" and "frequent users" in each age and sex group. Four age ranges were categorized by 10-year intervals (20–29, 30–39, 40–49, and 50 and over).

We calculated scores for each NHP dimension in these studies by adding all the answers to the items in the dimension, giving the value of 0 for answers of "no" and 1 for answers of "yes". To obtain a final score in each dimension, and to overcome the fact of having a different number of items in some of the dimensions, each sum was multiplied by 100 and divided by the number of items in the dimension. Possible scores ranged from 0 (all answers of "no" in the dimension, denoting absence of distress) to 100 (all answers of "yes", denoting maximal distress). Statistical significance was assessed using nonparametric tests (one-tailed Wilcoxon-Mann-Whitney, and Kruskal Wallis tests at a 5 percent level of significance[22]) because NHP responses do not follow a normal distribution.[9]

Mean scores of the NHP for the general population ages 41 and over of the city of Barcelona are presented in Table 1. Highest mean scores corresponded to Sleep and to Emotional Reactions (23.2 and 20.8, respectively), while the lowest was that of Social Isolation (7.2). Women scored considerably higher than men in all the dimensions. Mean scores were higher for social classes IV–V (manual workers) than for social classes I–II (directors, professionals and others).

People rating their health as "very good" scored 2.9 in Energy, 3.7 in Pain, and 4.9 in Social Isolation, as compared with those with "poor" or "very poor" health, scoring 64.3, 58.0, and 21.4, respectively (Table 2). People with at least one of the 34 chronic conditions listed scored significantly higher than those not reporting any condition, the score being higher as the number of conditions increased. Similar differences in

TABLE 1—Mean Scores for each Dimension of the Spanish Version of the NHP in the General Population Ages 41 and over of Barcelona.

	Energy	Pain	Emotional Reactions	Sleep	Social Isolation	Mobility (n)

**Wilcoxon-Mann-Whitney one-tailed test: $p < 0.0001$, for all dimensions.

size and direction were found for chronic limitation of activity and for restricted activity days (Table 2). Logistic regression analysis showed that NHP scores remained significantly associated with the construct validity variables, when age, sex, and social class were taken into account.

As shown in Table 3, the mean scores in each of the NHP dimensions were higher for the "frequent users" than for the "non-users." The most important relative differences corresponded to Pain and Energy dimensions (50 percent or more increase). Also, people reporting better health scored lower than those reporting worse health. NHP scores showed an ascending gradient related to reported number of chronic conditions (Table 3).

Discussion

Accurate translation is a first requirement in the process of transferring a health measure from the culture of origin to another culture.[2,5,15,23] However, it is a common practice that researchers themselves directly translate health questionnaires using technical and/or uncommon expressions which can affect validity, reliability, and comparability of results.

The translation methodology used for transferring the NHP into Spanish ensured a conceptually equivalent version.[24] The high level of agreement achieved in most back-translated items supports this equivalence. The participation of the monolingual lay panel in the translation ensured that statements of the new version were based on lay

TABLE 3—Mean Scores for each Dimension of the Spanish Version of the NHP by "Non-users" and "Frequent Users" and by other Convergent Validity Variables: Study of the Health Center of Barañain (Pamplona) (n = 276)

Characteristics	Energy	Pain	Emotional Reactions	Sleep	Social Isolation	Mobility (n)
Use of Health Services**						
Non-users	8.7	8.3	16.9	16.7	6.4	10.2 (138)
Frequent users	13.0	13.8	23.9	23.8	8.8	13.8 (138)

**Wilcoxon-Mann-Whitney one-tailed test: $p < 0.05$, for all dimensions.

expressions of health perceptions, as the original instrument. The fact that similar expressions had been obtained for other European versions of the NHP, further suggests that NHP items address aspects of health perceptions that have conceptual equivalence for these cultures.[7,13]

As mentioned above, the strategy for transferring the NHP into Spanish included the assessment of validity of the version before obtaining the weights of the items. As there is no gold standard against which validity of complex health status measures could be evaluated,[1,25,26] construct validity rather than criterion validity of the Spanish version has been assessed.

The results of the studies presented preliminarily suggest that the unweighted Spanish version of the NHP has construct validity. Mean scores in every NHP dimension are clearly different for individuals with diverse degrees of perceived health as assessed by a variety of other construct validity variables. All differences were in the expected direction: the lower the level of the perceived health indicator the higher the NHP score. The similarity of the results from both studies, with different designs and populations, further supports the validity of the questionnaire.

A similar distribution of NHP scores across different self-rated health (SRH) categories has been observed in several studies in Britain.[9,27,28] SRH has been shown to be a good predictor of health outcomes, even after adjusting for a number of variables including "objective" health status.[29,30] The consistency and the strength of the relationship between NHP scores and SRH is evidence of the validity of the questionnaire. In both studies presented, an increase was observed in mean NHP scores as the number of chronic conditions increased. Even though the severity of the conditions included was not considered, and the fact that conditions reported may reflect both medically diagnosed and patient perceived health problems,[31–33] it was expected that, on the average, people reporting more health conditions would have a worse perception of their health.

The approach of the first study for assessing construct validity, i.e., to compare scores for the new measure for different levels of self-reported health variables, has been previously utilized.[26,34,35] Most of these studies have reported high correlations among the health measures and the construct validity variables, similar to the results presented for the Spanish NHP. However, the relationship found between NHP responses and construct validity variables may be overestimated as responses to both were obtained directly by the respondent.

Conversely, in the second study, the number of visits was obtained from clinical records, independently of the measure of the responses to NHP. Thus, mean score differences between non-users and frequent users provide further evidence of the validity of the Spanish version of the NHP. However, these differences, although statistically significant, are not very large. This seems to be due to the fact that the scores of the "frequent users" are not so high as might be expected. The most likely explanation of this could be that people in the poorest health were misclassified due to a reduced likelihood of home visits by the doctor being recorded. Another explanation can be found in the fact that many of the "non-users" are non-symptom-free. A comparison of the distribution of health problems suggests that highest differences between these two groups were for conditions which have low potential impact on NHP scores (e.g., hypertension and hearing problems).

Nevertheless, to completely assess the equivalence of the questionnaire, similarity of the weights of the items should be established, as it has been done for other NHP European versions[7,13] and for the British version of the Sickness Impact Profile.[6] As mentioned above, the British authors of the NHP developed weights for the items in each dimension, using Thurstone's method of paired comparison;[14] weights being calculated by considering the proportion of times each statement was judged to be more severe than each of the other statements in the dimension by a representative group of lay people.

Developing the weights for the Spanish version would provide an important basis for definitively assessing validity of the questionnaire and for ensuring cross-cultural comparability.

APPENDIX

English and Spanish Versions of Selected Items of the Nottingham Health Profile (and graded agreement of back-translation)

British Item	Spanish Item	(Agreement)
Energy		
The days seem to drag	Los días se me hacen interminables	(A)
I'm tired all the time	Siempre estoy fatigado	(C)
Pain		
I have pain at night	Tengo dolor por las noches	(A)
Emotional Reactions		
Worry is keeping me awake at night	Las preocupaciones me desvelan por la noche	(A)
I lose my temper easily these days	Ultimamente me enfado con facilidad	(B)
Things are getting me down	Las cosas me deprimen	(C)
Sleep		
I take tablets to help me sleep	Tomo pastillas para dormir	(A)
I'm waking in the early hours of the morning	Me despierto antes de hora	(C)
Social Isolation		
I'm finding it hard to get on with people	Me cuesta llevarme bien con la gente	(A)
I'm finding it hard to make contact with people	Ultimamente me resulta difícil contactar con la gente	(C)
Physical Mobility		
I can only walk about indoors	Sólo puedo andar por dentro de casa	(A)
I find it hard to reach for things	Me cuesta coger las cosas	(C)

(A) Satisfactory translation
(B) One or two words uncertain
(C) Doubtful translation

New NCHS Report on Testing Fitness and Physical Activity

Assessing Physical Fitness and Physical Activity in Population-Based Surveys is a new report from the National Center for Health Statistics. The publication is a comprehensive review of the state-of-the-art and future directions in testing fitness and measuring physical activity.

The objectives set for the nation to improve health status through disease prevention and health promotion depend, in part, upon changing patterns of physical fitness and increasing levels of physical activity in the population. This reference volume is a comprehensive review of many topics associated with fitness testing and measurement of physical activity, including:

- Design issues and alternatives in assessing physical fitness among healthy adults as well as special populations;
- Assessment of energy turnover, energy intake or energy expenditures;
- Fitness and activity assessment of special populations of children, adolescents, women, and older adults;
- Evaluation of the health effects of demanding work on and off the job;
- Effects of physical activity and fitness on health; and
- Evaluation of the interrelationships among physical fitness and activity assessments and the epidemiologic uses of general population assessments of physical activity patterns and physical fitness.

Assessing Physical Fitness and Physical Activity in Population-Based Surveys can be purchased for $31; stock no. 017-022-010224, from the Superintendent of Documents, Government Printing Office, Washington, DC 20402.

Evaluating Community-based Nutrition Programs: Assessing the Reliability of a Survey of Grocery Store Product Displays

Allen Cheadle, PhD, Bruce Psaty, MD, PhD, Edward Wagner, MD, MPH, Paula Diehr, PhD, Thomas Koepsell, MD, MPH, Susan Curry, PhD, and Michael Von Korff, PhD

Abstract: A pilot test of a survey of grocery store product displays was conducted to measure the amount of health-education information provided and the proportion of the display devoted to "healthier" products. Inter-rater reliability ranged between 0.73 and 0.78 for the healthiness indices and between 0.30 and 0.67 for the health education measures. Test-retest reliability ranged from 0.44 to 1.0. (*Am J Public Health* 1990; 80:709–711.)

Introduction

There have been a number of recent efforts directed at entire communities to modify dietary behavior in order to reduce the risk of cardiovascular disease and cancer.[1–4] Evaluation of these interventions requires "community-level indicators" of program effectiveness—measures of the community environment that are not merely aggregates of individual behavior.[5] We measured the reproducibility of a survey of grocery store product displays to be used as part of the evaluation of community-based nutrition programs. Such surveys are particularly useful when grocery stores and supermarkets play a role in the intervention, as in the Giant Foods project[1] and in the Henry J. Kaiser Family Foundation Community Health Promotion Grants Program (CHPGP).*

Methods

We surveyed four general product areas within each grocery store: fresh produce, meat, milk, and bread. For each major product area, two types of information were recorded: presence or absence of health-promotion items, and the physical dimensions of product displays. The protocol took 30–45 minutes for an experienced rater to complete.

- *Health-promotion items* were defined as health education activities (usually printed material) on or near the displays, which provided nutritional information or increased awareness of healthy food choices, and which were independent of product packaging. Examples of health-promotion items included: shelf labeling, posters, recipes, and store health-information centers.
- *The measurements of the displays* were designed to create an index of the relative amount of space occupied by "healthy" products in each product area, calculated as the proportion of shelf space devoted to such products (e.g., those low in fat) relative to the overall size of the display of similar foods.

The sampling frame consisted of full-service supermarkets, defined as grocery stores with two or more check-out stands, carrying fresh produce and fresh meat, that were listed in the Yellow Pages telephone directory. The sample for the Seattle pilot test of inter-rater reliability included 13 independent stores and 24 chain stores. For this part of the field test, each store was surveyed by two raters who visited the four product areas in a different sequence. Test-retest reliability was evaluated on an additional random sample of 61 stores in five communities that are part of the overall Kaiser Foundation evaluation. These test-retests were carried out by the same rater on some occasions and by different raters on others, with a variety of time intervals separating the visits.

Three indices of display "healthfulness" are presented here: the proportion of poultry and fish in the meat display, the proportion of reduced-fat milk in the milk display, and the proportion of 100% whole wheat bread in the bread display. Health promotion items were coded simply as present or absent for each of the major product areas. To assess reliability, we used the intra-class correlation coefficient[6] for the continuous variables and weighted kappas[7] for the discrete variables.

Results

As Table 1 shows, chain stores (particularly national or regional chains) more often offered health promotion items than did independent stores. By contrast, there was little apparent difference in the three display variables by store type. Table 2, column (1) gives inter-rater reliability coefficients computed for the first visits to the 37 stores in the pilot sample. Reliability for the display variables was fairly high, in the range of .7 to .8, but was lower for the health promotion items. The low figures for the milk and meat health promotion items were partly due to an open-ended format for recording these items in the pilot survey; a closed format used in the later surveys produced better results. The figures in column

TABLE 1—Means of Grocery Store Survey Variables, by Store Ownership Category, Seattle Pilot Test Stores

Variables	Independent (n = 13)	Chains		
		Local (n = 13)	National/Regional (n = 12)	All (n = 37)
Health promotion items[a]				
Produce display	46.1	50.0	100.0	64.9
Meat display	69.2	100.0	100.0	89.2
Milk display	30.8	41.7	50.0	40.5
Display variables[b]				
% Poultry + fish	44.4	50.6	43.8	46.2
	(4.9)	(6.9)	(5.8)	(6.5)
% Reduced-fat milk	67.9	66.6	62.5	65.7
	(8.9)	(6.4)	(9.8)	(8.6)
% Whole-wheat bread	5.9	5.8	4.4	5.4
	(2.7)	(2.1)	(1.2)	(2.1)

NOTES: Standard deviation in parentheses.
[a]Percent of stores with health education materials in the indicated section. Store was counted as having health promotion items if either of the two raters recorded them.
[b]Percent of the display with indicated products. Measurements for each store are the average of the two raters. Definitions for numerator and denominator were as follows:
Meat: Shelf space occupied by poultry and fish/Total
Total = Fresh meat only; excludes frozen, canned, smoked or otherwise processed meat.
Milk: Shelf space occupied by 2% fat and skim milk/Total
Total = 2% fat, skim and whole milk only (half-gallon cartons)
Bread: Shelf space occupied by 100% whole wheat bread/Total
Total = Sliced, packaged loaves; excludes specialty bakery section, desert pastry, french bread, baguettes.

TABLE 2—Reliability Coefficients for Display and Health Promotion Item Measurements[a]

Variables	Different raters, same occasion[a]	Different raters, different occasions[b]	Same rater, different occasions[c]	Same rater, same occasion[d]
	(n = 37)	(n = 15)	(n = 27)	(n = 19)
Health promotion items				
Produce display	.67	1.00	.92	—
Meat display	.36	.63	.91	—
Milk display	.30	.46	1.00	—
Display Variables				
% Poultry + fish	.78	.86	.44	.98
% Reduced-fat milk	.75	.68	.58	.91
% Whole-wheat bread	.73	.47	.65	.93

[a]Statistical methods:
Display Variables: Intra-class correlation coefficients
Health Promotion Items: Weighted kappas
[a]Site: Seattle, WA (n = 37 stores)
[b]Site: Solano County, CA (n = 15)
[c]Sites: San Francisco, CA (n = 15), Orange County, CA (n = 12)
[d]Sites: Santa Cruz, CA (n = 15), Fresno, CA (n = 4)

(2), Table 2, show the correlations between two raters over a one-week time interval. This should approximate contemporaneous inter-rater reliability measures since few changes in health education materials were likely to have been made in this brief period. The revised format raised inter-rater reliability for the meat and milk displays—to 0.63 to 0.46, respectively.

The intra-class correlation coefficients presented in column (4), Table 2, all above 0.9, indicate high reliability in the same rater measuring the same display twice. Thus, most of the variation between occasions by the same rater was due to changes made by stores. The relatively high coefficients for health promotion items in column (3) suggest that these changed infrequently for the time intervals represented here. Display items showed lower intra-class correlation coefficients over time, particularly the meat display.

Discussion

Although sales data would reflect consumption most accurately, these are often unavailable to researchers. In the alternative measures which we used, measurements were made unobtrusively, and all of the stores approached for the pilot test agreed to participate; the response rate for the main study was 88 percent. Inter-rater reliability in the pilot was relatively high, particularly for the display variables. The lower inter-rater reliability figures for the health promotion items may have been due to the one-week interval between rater visits although, as noted earlier, significant changes were unlikely to have been made in that brief period. Test-retest reliability results indicated that both health promotion and display measures were relatively stable over periods ranging from one week to two months. Validity of the approach is currently being assessed, first by comparing the grocery store measures to the socioeconomic characteristics of people in the surrounding area, and second by correlating the survey measures with responses to dietary surveys of randomly sampled individuals living near the stores.

Poison Control Center Follow-up of Occupational Disease

EDDY A. BRESNITZ, MD, MS

Abstract: We followed up 73 of 372 calls to a Regional Poison Control Center (RPCC) that involved workplace disease/exposure(s); most other calls were not made by the workers. An average of 12 additional people per workplace were potentially exposed. Six of the 73 contacted a government agency for investigation of the hazard/illness. Twenty-five percent of callers were still exposed an average of seven months after the original call. The results indicate that poison control centers should develop a public health component to calls about possible workplace poisonings. (*Am J Public Health* 1990; 80:711–712.)

Introduction

An accurate estimate of the incidence of occupational disease in the United States is hampered by the lack of an active surveillance system.[1–4] Investigators have proposed using existing data systems including regional poison control centers[5,6] for passive surveillance of occupational disease. A call may represent a group of affected/exposed workers and serve as a sentinel health event that identifies hazardous worksites.[7]

We conducted a follow-up survey of individuals with occupational exposure/disease who contacted the Delaware Valley Regional Poison Control Center (DVRPCC), over a 12-month period.

Methods

Approximately 7,760 individuals over the age of 17 contacted the Delaware Center between July 1, 1986 and June 30, 1987. Information was recorded on the American Association of Poison Control Centers' precoded report form. Referral guidelines listing the telephone numbers of outside agencies to which occupationally related callers may be referred are available to staff. The guidelines indicate that calls or complaints about known Occupational Safety and Health Administration (OSHA) regulated substances should be referred to OSHA and complaints about substances not covered or enforced by OSHA should be referred to the National Institute for Occupational Safety and Health (NIOSH).

A workplace exposure was recorded on the intake form of 372 calls (4.8 percent). Trained personnel, unrelated to the poison control center, abstracted data from these intake forms and called the telephone number obtained during the initial encounter. These follow-up calls were made between July 1 and November 1, 1987, an average of seven months after the initial call.

The interviewer explained the purpose of the study to the affected worker and obtained informed consent. To proceed, the interview was then either administered immediately or within one week at a prearranged time. In three cases, the interviewee was the sentinel case's employer who answered the questions from his/her perspective. Interviewers used a pre-tested, pre-coded form containing predominantly closed-ended questions. The analysis included 95% confidence intervals for differences in proportions.[8]

The study protocol was reviewed and approved by the Committee for the Protection of Human Subjects of the Medical College of Pennsylvania and the Medical Advisory Panel of the DVRPCC.

Results

The interviewers successfully interviewed 73 of the 372 work-related calls. Table 1 compares the characteristics of the 73 workers interviewed and the 299 workers not interviewed from information on the Center's intake form. Of those not interviewed, 209 (69.9 percent) calls originating from medical personnel or hospitals were excluded, because we did not believe that our questions would be answered without the patient's consent. Forty-nine callers (16.4 percent) either left no telephone number or gave a disconnected or false number. Of the remainder, 16 (5.4 percent) had been terminated from their jobs, 15 (5 percent) refused to answer questions and one (.3% percent) was an informational call.

The interviewed workers (responders) had acute exposures to more than 60 different chemicals at 73 different worksites; 19 individuals were exposed to two or more substances. All but four of the affected workers were symptomatic at the time of the initial call.

The responders had worked an average of 5.5 years at the worksite where the exposure occurred at the time of the follow-up call. Forty-nine (67 percent) of the 73 responders indicated that other workers (mean of 12) had been exposed

TABLE 1—Comparison of Interviewed and Non-Interviewed Workers Based on Information from Poison Control Center (PCC) Intake Form

Characteristics	Exposed Workers Interviewed (N = 73)	Exposed Workers Not Interviewed (N)	95% CI of Difference
Mean Age (years)	30.8	30.5 (229)	
Sex (%)			
Male	66	78 (277)	(−23.9, 0.1)
Female	34	22	
Site of Caller (%)			
Residence	63	13	(38, 62)
Workplace	34	15 (289)	(7, 31)
Health Care Facility	3	72	(−75, −63)
Hospitalized (%)	0	6 (186)	(−12, −4)
PCC called back within 24 hours (%)			
Yes	69	59	(−2, 22)
No	31	37 (288)	
Tried and Failed	0	3	
Referral to Other Non-Medical Agency (%)			
Yes	6	15 (246)	(−16, −2)
No	94	85	
Route of Exposure			
Inhalation	67	42	(13, 37)
Ocular	11	32 (289)	(−30, −12)
Dermatologic	21	20	(−9, 11)
Ingestion	1	6	(−9, 11)
Parenteral	0	0	

at their worksite. Eight (16 percent) of these 49 responders indicated that one or more co-workers had been out on sick leave for the same exposure.

Overall, 48 responders reported they were advised to call their physician; 75 percent of these complied with this advice. Poison center staff recorded referrals to outside agencies in only four of the 73 calls (5 percent). However, 10 (14 percent) responders stated they were advised to call either OSHA, NIOSH, or the local health department. Five of seven reported that they called OSHA. One receiving a recommendation to call the health department or NIOSH did so.

Twenty-five of the 47 responders who approached their employer reported the institution of one or more primary preventive measures. Seven responders indicated that they were either fired or harassed or transferred.

Table 2 describes other issues assessed in the study. Only 37 percent of the responders had heard of either municipal, state, or federal right-to-know legislation, most frequently in the workplace or in the media. A responder was more likely to have heard about right-to-know laws if he/she had been hired less than one year prior to their initial call (62.5 vs 30 percent, 95% CI of difference = 5, 60).

TABLE 2—Other Public Health Issues Assessed in Responding Workers at Follow-Up

Health Issues (N)	Yes % (N)	95% CI
Worker still exposed (73)	25 (18)	16, 36
Existence of workplace union (70)	23 (16)	14, 34
Health and safety person present in workplace at time of exposure (e.g., employer, manager) (69)	49 (35)	37, 61
Worker still having health problems (72)	4 (3)	1, 12
Suffered disability or work loss (72)	32 (23)	21, 41
Sick leave covered by Workers' Compensation (23)	22 (5)	8, 44
Currently seeing physician (71)	4 (3)	1, 12
Caller heard about right-to-know law (73)	37 (27)	26, 49
Caller read material safety data sheet (69)	17 (12)	9, 28

Discussion

The data reveal that poison center staff infrequently referred occupationally related calls to agencies concerned with occupational health despite existing guidelines and may not have routinely documented such information. Referred callers tended to follow poison center staff advice when given.

Blanc and Olson[5] determined that many more occupationally related cases were enumerated through a state-mandated physician-initiated active reporting system than through a passive system such as a poison control center. Our study supports this finding.

Although we studied a selected sample of workers, the survey most likely underestimates the potential magnitude of the problem. The majority of those not reached were workers evaluated in a health care facility or admitted to hospitals. A greater percentage of those not reached were hospitalized, indicating more severe medical problems and, perhaps, more serious workplace hazards in this group.

Poison control centers reported that 6.8 percent of approximately 312,000 calls from adults in 1987 were related to exposures in the workplace.[9] Although this data base appears to be a source of supplementary surveillance data for occupational illness, if our experience represents that of other centers, the staff may need to modify their protocols and improve their public health approach to callers with occupationally related illness/exposures. Centers could refer all workplace-related calls to a separate state or federal agency responsible for hazard evaluation and follow-up. Failure to investigate these calls may result in continued exposure and illness in all workers connected to an index case.

ACKNOWLEDGMENTS

The author expresses gratitude to Sally Kirkpatrick and Kate Kraft for their assistance in data collection and coding; to Ed Gracely for statistical analysis and critical review; and to Carolyn Needleman, Kathleen M. Rest, Harriet Rubenstein, Thomas Kearney, and Fred Henretig for their helpful comments. Illegal Abortion in Mexico: Client Perceptions

Susan Pick de Weiss, PhD, and Henry P. David, PhD

Abstract: An exploratory study of the perceptions of 156 abortion clients in Mexico suggests that perceived quality of service was the main reason for choosing physicians while cost and anonymity were the major reasons for choosing nonphysicians. "Too young" was the most often cited reason for pregnancy termination, followed by economic situation and having too many children already. Cost was, on average, equivalent to three to four weeks minimum wage; physicians' charges were about three times higher than those of nonphysicians. (*Am J Public Health* 1990; 80:715–716.)

Introduction

In Latin America, abortion is legally restricted everywhere except in Cuba.[1] In Mexico, abortion is legally permitted only for reasons of health, rape, or incest.[2] Contraceptive services are widely available, especially in the cities.

The public health, economic, social, and psychological costs associated with the illegal termination of unwanted pregnancies have been repeatedly documented[3–6]. Complications of clandestine abortions presently constitute the fifth largest cause of maternal mortality and the third highest reason for admission to gynecological services in the metropolitan hospitals of the Mexican Social Security System; no reliable data are available on women admitted to other services.[7]

To obtain information on the perceptions of women seeking clandestine abortions in Mexico, an exploratory study was conducted in Mexico City, Acapulco, and Oaxaca. Another objective was to test the feasibility of conducting behavioral research in an area of public health that throughout much of the region is culturally taboo and severely restricted by law.

Methods

Twelve experienced female graduate and undergraduate psychology students, sensitive in conducting individual interviews, some of whom had had abortions, were trained by the senior author (SPdW) to seek out personal acquaintances who had terminated unwanted pregnancies illegally in the recent past. On completion of interviews the subjects were invited to suggest other possible study participants. Of 159 women known to have had at least one induced abortion in the recent past, 156 agreed to individual interviews. The questionnaire was composed of mostly open-ended items that had been field-tested. Interviewees were assured of anonymity and confidentiality of replies.

Results

Of the 156 women, 119 had their abortion performed by physicians, 32 by untrained service providers, and five could not recall their providers' qualifications. As shown in Table 1, of the women attended by a physician most were not married. Ages ranged from 12 to 56 years; clients attended by physicians were significantly older and better educated than those seen by others. More professional women were seen by physicians. Over one-third of the women had at least one child.

A lower proportion of clients attended by physicians had experienced two or more abortions compared to those seen by nonmedically trained persons. Most of the procedures performed by physicians occurred in a private clinic or hospital (91.6 percent), while other service providers generally operated in the client's home. Quality of service was the most frequent reason for going to physicians (30.8 percent), followed by security, while cost (56.2 percent) was the main reason for seeking other providers, followed by security and anonymity. As also shown in Table 1, when asked in an open-ended question without probe, the most often cited reason for having an abortion among all women was becoming pregnant at too young an age. Another major reason among physician-attended women was the partner's rejection of the pregnancy. Among women attended by untrained providers, the second and third reasons were economic and having too many children already.

No differences between the two groups were noted among cited referral sources which included friends, sexual partners, family members, physicians, and psychologists. About half the physician-attended women considered the location of the service far away from their home compared to 25 percent of those attended by untrained providers. The cost of a physician-induced procedure was, on average, the equivalent of three to four weeks legal minimum wage in Mexico. A physician-provided service was generally two to three times more expensive than that provided by others ($88 vs $33 in 1987/88). Among women attended by physicians 43 percent reported receiving contraceptive counseling in connection with their abortion, compared to only 3 percent of those who went to other providers.

As further shown in Table 1, for the women attended by physicians, the most often reported procedures were curettage; over one-fifth did not know what procedure had been

TABLE 1—Characteristics of Two Groups of Woman Who Had Induced Abortions, Mexico

Characteristics	Physician Attended (n = 119)	Other Attended (n = 32)	Difference	(95% CI)
Mean Age	26.2	24.5	1.7	(−.85, 4.25)
Mean No. of Children	1.97	2.06	−0.09	(−.9, .72)
Average Cost in Dollars	88	33	55	(45.2, 64.8)
	Percentages			
Single	67	59	8	(−9,25)
Attended College	39	25	14	(−9,37)
Professional Occupation	19	4	15	(8,22)
Two or More Abortions	13	22	−9	(−36, 18)
Received Contraceptive Information	43	3	40	(15, 65)
Post-abortion Problems	22	47	−25	(−53, 3)
	Procedure Used			
Curettage	50	13	37	(15, 59)
Catheters	3	19	−16	(−46, 14)
Injections	3	25	−22	(−51, 7)
Suction	20	–	–	(–)
Wire, Needles, Herbs	–	29	–	(–)
Unknown to Woman	24	13	11	(−17, 39)
	Reason for Abortion			
Too Young	31	34	−3	(−27, 21)
Partner Pressure	39	13	26	(1, 51)
Too Many Children	8	16	−8	(−38, 22)
Economic	15	19	−4	(−32, 24)
Other Reasons	7	18	−11	(−41, 19)

used. Among the women attended by untrained service providers, the most often cited procedures were injections, catheters, herbs, curettage, and wires or needles; few did not know what procedure was used.

Before going to a service provider, almost two-thirds of all the women had purchased pseudoabortifacients without adequate knowledge of possible risks. About one-third of all the women had tried inducing an abortion themselves, resorting to herbs, injections, or a combination of both, or of either with pills, hard exercise, or the introduction of objects into the cervix. Post-abortion complications were noted by less than one-fifth of the physician-attended women (mostly cramps) compared to nearly half of those attended by untrained providers who noted more hemorrhages (22 percent vs 47 percent). When asked if they would recommend their provider to other women, three-fourth of the physician-attended women replied affirmatively compared to one-fourth of those attended by other service providers.

Discussion

It is recognized that the findings from this exploratory study are limited by the nonrepresentativeness of the sample. However, the responses obtained confirm informal impressions that nonmedically trained persons provide abortion services primarily to women of lower socioeconomic and educational levels, and that such women are at greater risk for experiencing post-abortion complications and for future unwanted pregnancies since contraceptive counseling is seldom provided.

The method of open-ended interviewing developed for this exploratory study appears suitable for further adaptation for behavioral research on the sensitive topic of abortion with more representative populations in those countries of the region where the procedure remains a taboo topic. In concert with more epidemiological research, such studies may be expected to contribute to a reexamination of the public health risks of legally restricted abortion and to motivate improved access to effective contraception that will reduce the future incidence of unwanted pregnancies.

ACKNOWLEDGMENTS

The authors wish to thank the UNAM (Universidad Nacional Autonoma de Mexico) psychology students who participated in data collection, Patricia Andrade-Palos for her comments on the manuscript, and the Population Crisis Committee for partial support of the study.

A Survey of State Medicaid Policies for Coverage of Abortion and Prenatal Diagnostic Procedures

JANET WEINER, MPH, AND BARBARA A. BERNHARDT, MS

Abstract: In the summer of 1988, we surveyed all states to evaluate access to Medicaid funding for abortion after the diagnosis of an anomalous fetus. All state Medicaid programs covered amniocentesis, and most had expanded coverage to include newer prenatal diagnostic procedures for eligible women. In 29 states, however, abortion coverage was limited to instances when continuation of abortion threatens the life of the mother. Only 13 states paid for a woman on Medicaid to obtain an abortion after diagnosis of an anomalous fetus. (*Am J Public Health* 1990; 80:717–720.)

Introduction

Medicaid is a joint state- and federally-funded program, enacted in 1965, to provide health care coverage for many indigent and disabled citizens. Within broad federal guidelines, each state has latitude in deciding which medical and ancillary services are to be covered by its Medicaid program.

In 1973, the US Supreme Court decision in *Roe v. Wade* prohibited states from interfering with a woman's right to abortion except to protect maternal health or a viable (third trimester) fetus. By 1974, three-fourths of the states covered most abortions under their Medicaid programs.[1]

In 1977, Congress passed the Hyde Amendment, which limited federal reimbursement of abortions to situations that threatened the life or physical health of the mother, and to victims of rape and/or incest. Current federal policy reimburses states only for abortions performed to save the life of the mother. Abortions for other reasons, which constitute over 99 percent of all abortions, must be paid for by non-federal or, in most cases, state funding.[2]

At present, increasingly sophisticated techniques such as amniocentesis, chorionic villus sampling (CVS), ultrasound, and biochemical assays are permitting earlier and broader detection of fetal abnormalities. Malpractice fears impel physicians to identify patients at risk for producing children with prenatally-diagnosable defects and offer them appropriate testing.[3] At least one state requires that maternal serum alpha-fetoprotein (MSAFP) screening be offered to pregnant women.[4] Ethical practice dictates that when tests show a fetal anomaly exists, the woman be offered the option of pregnancy termination, within the guidelines of each state's law regulating abortion.[5] Information has been unavailable nationally on coverage of prenatal diagnostic services by Medicaid programs and on utilization of these procedures by pregnant Medicaid recipients.

The survey reported here delineates state-by-state Medicaid guidelines for coverage of prenatal diagnostic procedures and abortion.

Methods

We developed a questionnaire that asked about Medicaid coverage of seven prenatal services: amniocentesis, ultrasound to rule out fetal anomalies, CVS, MSAFP testing, fetal DNA analysis, chromosome analysis on cultured amniotic fluid cells, and genetic counseling. We included the standard Current Procedural Terminology Codes for each procedure (when available). Respondents were asked to check either "covered", "not covered", "covered on a case-by-case-basis", or "unknown" for each procedure. We asked about Medicaid coverage of abortion for seven indications, broad enough to encompass the variation in state policies, using the legal terminology of indications for abortion as reported in the Medicare and Medicaid guide.[6]

We mailed the questionnaire to the director of the Medicaid program in each state and the District of Columbia. After follow-up, including telephone calls, the final response rate was 100 percent. We did not attempt to verify how completely these guidelines were followed in each state. The responses reflect Medicaid regulations as of summer 1988.

Results

Each state's coverage of prenatal diagnostic procedures is shown in Table 1. The majority of states cover all procedures listed, and almost all have developed guidelines for coverage, as indicated by the low numbers of "case-by-case" or "unknown" responses. All states and the District of Columbia cover amniocentesis, and all but one cover MSAFP testing. Two-thirds cover CVS and three-fourths cover DNA analysis, both of which are newer technologies for the detection of fetal abnormalities.

Table 2 lists each state's coverage for abortion. At the time of the survey, seven states and the District of Columbia paid for abortion on demand. All states cover abortions that save the life of the mother, the only ones for which federal reimbursement is available. In 29 states, this is the *only* indication for which Medicaid will cover an abortion. Eleven states will pay for abortion when the indication is a known or suspected fetal anomaly, and two other states evaluate coverage on a case-by-case basis. Just over one-fourth of the states will pay for "medically necessary" abortions, usually as certified by an attending physician. Likewise, victims of rape and/or incest are covered for abortion in one-fourth of the states. This indication has been hotly debated on a federal level, as President George Bush recently vetoed a congressional package that would have reinstated federal reimbursement for abortion in cases of rape and incest.

Discussion

A combination of Medicaid regulations has led to the incongruous policy in many states of covering prenatal diagnostic services but not the selective abortion in cases of a diagnosed fetal abnormality. We believe that these policies

discriminate against poor women and interfere with ethical medical practice. By covering prenatal diagnostic services in Medicaid programs, each state in this country acknowledges the medical necessity of these services and its commitment to providing access to them. Since abortion is a recognized option for women carrying an anomalous fetus, states that refuse to pay for abortion interfere with women's rights. Once a state has agreed to pay for diagnostic procedures, we do not believe it should influence subsequent medical decisions.

In the future, Medicaid guidelines will affect more and more women, as Congress encourages states to expand eligibility criteria for pregnant women. By July 1990, federal Medicaid guidelines mandate that all states cover pregnant women at poverty level, and will give states the option of covering women with incomes up to 185 percent of poverty

*Since the fall of 1986, Michigan and Colorado, by voter referenda, and the District of Columbia, by legislative action, altered their regulations to pay only for life-threatening abortions.

level.[7] Therefore, the public health implications of Medicaid policies on abortion will become even greater.

As budgetary pressures force state and federal agencies to cut costs, the economic burden of restrictive abortion funding will loom larger. The financial cost of the Hyde Amendment was estimated conservatively to be $95 million in 1986. For every dollar spent on a desired abortion through Medicaid, four dollars are saved in medical and social welfare costs in just two years.[8] The medical and emotional costs of bearing children that are either not wanted or have major anomalies may be far greater.

Health care costs of infants and children with genetic disorders and chronic illnesses are at least three times higher than those of other children.[9] Those born to low-income families pose an even greater challenge to an already overburdened household. Children with disabilities require addi-

tional health care services including occupational and physical therapy, psychosocial support, home health care, respite and day care.

On a state level, Medicaid policies on abortion have been heavily influenced by political pressure from right-to-life groups. Since our survey, two states (Colorado and Michigan) have altered their regulations because of referenda placed on the ballot in the November 1988 elections, and the District of Columbia has withdrawn funding entirely. Regardless of one's views on abortion, we believe the Medicaid program should not be used to force the poorest women among us to bear children with severe congenital anomalies.

Obstetrical Pulmonary Embolism Mortality, United States, 1970–85

ADELE L. FRANKS, MD, HANI K. ATRASH, MD, MPH, HERSCHEL W. LAWSON, MD, AND KAREN S. COLBERG, BA

Abstract: To investigate pulmonary embolism as a cause of obstetrical death, vital records data from 1970 through 1985 were analyzed. Results showed that the number of obstetrical pulmonary embolism deaths per 100,000 live births declined by 50 percent for both Whites and Blacks. However, Black women maintained more than a 2.5-fold higher risk, and women over age 40 had a ten-fold higher risk of embolism mortality. Thus, although the risk of obstetrical pulmonary embolism death has declined, some subgroups of women remain at higher risk. (*Am J Public Health* 1990; 80:720–721.)

Introduction

Several studies of maternal mortality have found pulmonary embolism to be the leading cause of maternal death in recent years.[1–5] It has been suggested that pulmonary embolism deaths may be becoming more important as a cause of maternal death because deaths due to other causes are declining more rapidly, or because medicolegal concerns favor the diagnosis of causes of death perceived to be nonpreventable.[1,4] Little is known nationally about trends in maternal mortality due to pulmonary embolism.

The purpose of the current analysis was to determine the absolute and relative importance of pulmonary embolism as a cause of obstetrical death over time on a national basis, and to describe the demographic risk factors for obstetrical pulmonary embolism (OPE) death.

Methods

The total number and characteristics of obstetrical deaths were obtained from multiple cause of death mortality tapes made available by the National Center for Health Statistics (NCHS). Up to 20 diagnoses are recorded from each death certificate and coded according to the International Classification of Diseases (ICD).[6,7] Obstetrical deaths were identified as those with any nonabortive pregnancy-related diagnosis (ectopic pregnancies, spontaneous abortions, induced abortions, and molar pregnancies were excluded). For the years 1970 through 1978 OPE deaths included ICDA-8 codes 634 and 673, while for 1979–85 they included ICD-9-CM code 673. These data do not allow one to separately identify amniotic fluid, thrombotic or air pulmonary embolism; therefore all causes of pulmonary embolism are grouped together.

The OPE mortality ratio is defined as the number of obstetrical deaths associated with pulmonary embolism per 100,000 live births during the same time period. The numbers of live births for each year were obtained from national natality computer tapes made available by NCHS. The OPE mortality ratios for both Blacks and Whites over time were standardized to the age distribution of White live births 1970–85.

The percent of obstetrical deaths due to embolism is the number of pulmonary embolism-associated obstetrical deaths per 100 obstetrical deaths during the same time period. The analysis is restricted to women over the age of 14 years and younger than 45 years who were classified as either White or Black.

Results

From 1970 through 1985 there were a total of 1,417 OPE deaths and 55,096,188 live births, for an overall OPE mortality ratio of 2.6 OPE deaths per 100,000 live births. Over the 16-year interval OPE mortality ratios, standardized by age, declined more than 50 percent for both Whites (from 3.3 to 1.3 per 100,000 live births) and for Blacks (from 9.0 to 4.2 per 100,000 live births) (Figure 1). However, Black women maintained more than a 2.5-fold higher risk of OPE mortality than White women throughout the 16-year interval. This racial disparity did not vary systematically over time or

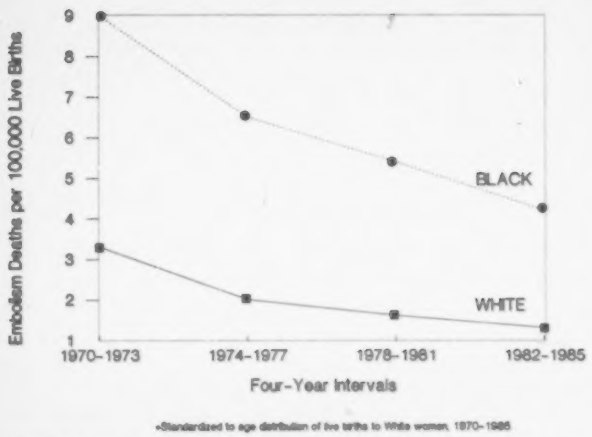

FIGURE 1—Obstetrical Pulmonary Embolism Deaths per 100,000 Live Births,* United States, 1970–85

between age groups. The percentage of all obstetrical deaths which were associated with pulmonary embolism did not differ between White and Black women, and remained relatively constant over time at approximately 25 percent.

Aggregating all 16 years under analysis, the absolute risk of OPE death increased with age for both race groups and was at least 2.5 times higher for Black women than for White women at all ages (Figure 2). For both racial groups, the risk for women 40 years of age or older was nearly 10 times greater than for women less than age 25.

Discussion

Although recent studies have found pulmonary embolism to be the leading cause of maternal death, vital records data show that the absolute risk of OPE death has been dropping and the proportion of obstetrical deaths associated with pulmonary embolism has not been increasing. Thus the belief that maternal pulmonary embolism deaths are a growing problem in the US is not supported by vital records data.

The limitations of vital records data in the surveillance of maternal death have been previously described.[8] Investigations designed specifically to identify and evaluate maternal deaths uncover more deaths, and often have more available information for assigning a cause of death. Indeed, vital records data do not allow clinical differentiation of immediate cause of death from underlying conditions which may contribute to death. We reviewed concurrent diagnoses from the death certificates of the OPE deaths under analysis. The most common concurrent diagnoses were cardiovascular disease, arrhythmia, shock or cardiac arrest (40 percent), hemorrhage or coagulopathy (17 percent), venous disease (9 percent), or "other ill-defined causes of morbidity or mortality" (9 percent). As these conditions could either precede or follow an OPE, inferences about which condition was the principal cause of death versus which conditions may have contributed to causing death cannot be made based on these data. However, we found no change over time in the distribution of concurrent diagnoses. In addition, we repeated our analysis using the single underlying cause of death as determined by NCHS. Results revealed trends over time and by race and age which were identical to those reported in this paper.

In this study we were unable to evaluate type of pulmonary embolism, although previous studies of maternal death have found half or more of maternal pulmonary embolism deaths to be thrombotic in nature.[1,3–5,9] Among causes of embolism, thrombotic events may be the most amenable to prevention through changes in medical/surgical practices.[10,11] Further research is necessary to characterize the temporal relationship between delivery and thrombotic events, as well as to identify potential risk factors for thrombotic death, such as method of delivery (vaginal vs cesarean section), personal characteristics (e.g., obesity), or underlying medical, surgical, or obstetrical conditions. With this information, interventions such as prophylactic use of pressure gradient stockings or anticoagulation[3] may be implemented and evaluated for those at highest risk. Unfortunately, vital records data alone cannot provide the increased clinical detail necessary to guide risk reduction strategies for this leading cause of obstetrical death in the United States; therefore much depends on current efforts to gather supplemental information about maternal deaths.[12]

Cervix and Breast Cancer Incidence in Immigrant Caribbean Women

RACHEL G. FRUCHTER, PHD, MPH, KAMRAN NAYERI, MA, JEAN CLAUDE REMY, MD, CAROLYN WRIGHT, MS, JOSEPH G. FELDMAN, DPH, JOHN G. BOYCE, MD, AND WILLIAM S. BURNETT, MD

Abstract: Cervix and breast cancer incidence in 1978–82 was computed for immigrant and United States-born Black women in Brooklyn, New York. Compared to the national SEER (Surveillance, Epidemiology and End Results) rates, US-born and Haitian women had high rates of invasive cervical cancer, while English-speaking Caribbean immigrants had an average rate. However, while US-born women had an average rate of carcinoma in situ of the cervix, both immigrant groups had low rates. Both immigrant groups had low rates of breast cancer, whereas US-born Black women had an average rate. (*Am J Public Health* 1990; 80:722–724.)

Introduction

Immigrant populations challenge the United States systems for preventive health care because they may differ from the US-born in their patterns of disease and in their knowledge and utilization of preventive health services. Where health statistics are recorded only by race, differences within populations may be obscured and information inadequate to plan effective programs.

In Brooklyn, New York City, about 20 percent of the Black community of about 700,000 are immigrants, primarily from the Caribbean basin. Haitian immigrants with invasive cancer of the cervix are diagnosed at a significantly later stage than US-born Black women,[1] and Haitians are less likely than US-born or English-speaking Caribbean women to have had a Pap test or to practice breast self-examination.[2] We determined the incidence of breast and cervix cancer among ethnic subgroups of the Black community in Brooklyn in order to help plan effective cancer prevention activities.

Methods

Population data from the 1980 US census were obtained from a 5 percent Public Usage Microdata Sample for Brooklyn. Birthplace was categorized as: 1) USA; 2) English-speaking Caribbean islands; 3) Haiti; and 4) Other. "Other" birthplaces included Africa, Europe, Canada, central and south America, and Spanish-speaking Caribbean islands. Birthplace was available for 92 percent of Black foreign-born women. For each five-year age group, foreign-born women of unspecified birthplace were allocated to above categories 2–4 in proportion to women of known birthplace. Cancer cases in Brooklyn residents from 1978–82 were obtained from the New York State Cancer Registry.[3] Cases were histologically confirmed in 93–99 percent depending on diagnosis.[3] Birthplace was not available for 8–14 percent of cases and was allocated as described for population data.

Although carcinoma in situ may be diagnosed in ambulatory facilities and therefore has potential for underregistration, low-income populations are usually dependent on hospital-based facilities and there is no reason to assume differential registration for immigrant and non-immigrant women.

For each group of Brooklyn women, we computed the age-standardized incidence ratio (SIR—observed:expected cases) comparing each group to the total Black US rates. We used the "indirect method" by applying the five-year age-specific rates for Black women from the 1978–81 data of the Surveillance, Epidemiology and End Results (SEER) program to the Brooklyn populations to obtain the expected numbers of cases.[4] The 95% confidence intervals (CI) of the SIR were computed from a Poisson distribution.[5] The indirect method was used because Haitian and "Other" groups had less than 50 cancer cases per site giving unstable age-specific rates.

The 1980 census undercounted low-income minority populations especially in areas with many immigrants.[6] Incidence ratios based on census data are therefore maximum ratios.[7] Since undocumented immigrants were probably recent arrivals, we assumed one uncounted immigrant of the same age, sex and birthplace for every two counted immigrants who entered the USA after 1969. This increased the English-speaking Caribbean adult female population by 23 percent, the Haitian population by 30 percent, and the "Other" population by 18 percent. We used this adjusted population to estimate *minimum* cancer incidence ratios, an arbitrary though "reasonable" maneuver that was necessary to assess the importance of unusually high ratios that might have programmatic implications.

Results

Incidence ratios for invasive cervical cancer were high for Haitian-born women, yet for carcinoma in situ, ratios were low for all three immigrant groups (Table 1). US-born women had a high incidence ratio for invasive cervical cancer but an average ratio for carcinoma in situ. For breast cancer all immigrant groups had low incidence ratios, whereas the ratio in US-born women indicated an incidence similar to the SEER rate. The SIRs cannot be compared to one another because they were not standardized to the same age distribution. When the population was adjusted for uncounted immigrants, all the SIRs were reduced, but relationships were essentially unchanged.

Selected characteristics of the four groups (excluding "other") are shown in Table 2. Immigrants had higher rates of high school completion and labor force participation and lower rates of poverty and fertility than US-born women in Brooklyn and Black women nationally.

Discussion

The incidence ratios reflect both the underlying prevalence of cervical neoplasia and the level of Pap smear screening. Factors consistently associated with a high prevalence of cervical neoplasia include low socioeconomic status (SES) and early sexual activity. These factors may account for the high incidence of invasive cervical cancer in US-born Black women in Brooklyn, also noted in Detroit, the major low-income, northern city in SEER.[8]

In the immigrant groups, the average to high rates of invasive cervical cancer combined with low rates of carcinoma in situ suggest low screening rates among all Black immigrants. Community and hospital studies of selected populations have consistently reported lower screening rates in immigrants than in US-born women.[1,2] A relatively low prevalence of cervical neoplasia in the Brooklyn immigrants may also be a possibility given their relatively high socioeconomic status and low early fertility (a proxy for sexual activity) reported in the census.

Cervical neoplasia among Haitian immigrants in Brooklyn has several unique features including: an unusually high incidence of invasive cancer (even when adjusted for a census undercount) with a high proportion in advanced stages,[1] and consistently lower screening rates than other Black women in community[2] and hospital populations.[1] Furthermore, two unpublished studies* suggest that Haitians have lower hysterectomy rates than other Black women in Brooklyn. First, in a community-site screening program, only 3 percent of 561 Haitian women had a hysterectomy compared to 17 percent of 378 English-speaking Caribbean immigrants and 14 percent of 319 US-born women. Second, among hospital inpatients with nongynecologic diagnoses undergoing routine cytology, none of 28 women with French names had a hysterectomy compared to 16 percent of 257 other Black women. In each study these differences held for all age groups, and the hysterectomy rates in the US-born and English-speaking Caribbean women were similar to rates in women in upstate New York.[9] Although conclusive evidence is lacking, we suggest that the uniquely high rate of invasive cervical cancer in Haitians may reflect a greater proportion of women with uteri at risk, low screening rates among Haitian immigrants in Brooklyn, and a severe lack of screening in deeply impoverished Haiti, where clinical and laboratory facilities are limited. A high rate of cervical neoplasia in Haitians has also been reported from Miami.[10]

TABLE 2—Selected Characteristics of Black Women in Brooklyn by Birthplace

Characteristics	Brooklyn Women by Birthplace			National data
	USA	ESC	Haiti

% Women over age 25 with education ≥ 12 grade	58.4	84.8	67.2	51.5
% Women ages 16 and over in labor force	45.8	67.0	63.2	53.3
% Persons with income below poverty	39.2	18.3	26.0	29.9

National data for Black women: US Census 1980.[12] Brooklyn data from Public Usage Microdata Sample for Brooklyn.

The finding of an average incidence of breast cancer among US-born Black women in Brooklyn underlines the value of examining ethnic differences, since the overall rate in Black women would otherwise appear encouragingly low. The below-average incidence of breast cancer in both Haitian and English-speaking Caribbean immigrants is consistent with other studies which show persistently low rates of breast cancer in migrants from countries with low incidence.[11] However, limited exposure to clinical breast examination and mammography among immigrants might also contribute to low rates of detection of occult breast lesions. The demographic characteristics indicate that other risk factors associated with high rates of breast cancer—high SES and delayed pregnancy—cannot explain the low rates in immigrants.

These findings indicate the importance of evaluating cancer rates in different ethnic groups in heterogeneous communities, and have particular implications for cancer prevention activities in cities with Caribbean immigrant populations. The low rates of carcinoma in situ suggest that more basic education and cytologic screening are needed. The uniquely high rate of invasive cervical cancer in Haitians, combined with linguistic and other barriers to care, warrant special programs for Haitian women. Finally, the most intensive efforts to promote breast examination and mammography should probably be focused on US-born women.

Ten-Year Changes in Birthweight Distributions of Black and White Infants, South Carolina

ROBERT M. MAYBERRY, PHD, AND ROBERT F. LEWIS, PHD

Abstract: The birthweight distributions of Black and White infants in South Carolina were compared for the paired-year periods 1975–76 and 1985–86. No discernible changes in birthweight distributions between the two time periods were observed especially among Black infants. The distributions among White infants reflected an overall improvement in birthweight most noticeably above 2500g. (*Am J Public Health* 1990; 80:724–726.)

Introduction

Birthweight is considered the most important predictor of infant mortality particularly for deaths occurring within the first 28 days of life.[1,2] While significant declines have occurred in infant mortality rates in the United States only slight declines in the incidence of low birthweight (<2500 grams) have been noted.[3,4] When noted, the declines were not observed for all segments of the population. Considerable racial differences persist; Black infants are twice as likely to be low weight at birth as White infants.[4]

South Carolina continues to have one of the highest infant mortality rates in the nation. Nevertheless, infant mortality rates and particularly neonatal mortality rates have declined substantially in the last decade. To determine whether improvement in birth weight has occurred in South Carolina, 1975–76 birthweight distributions of Black and White infants were compared with those of 1985–86.

Methods

Reported birthweights of infants born to mothers residing in South Carolina at the time of birth were obtained from public tapes of matched births and deaths provided by the Office of Vital Records and Public Health Statistics, South Carolina Department of Health and Environmental Control. Sex-specific birthweight distributions for Black infants and White infants were compared for the paired-year periods 1975–76 and 1985–86. Five-ounce weight classes were chosen to reflect the original measurements (ounces) and to adjust for propensity to report in quarter-pound units for infants weighing near average. Cumulative frequency distribution curves for each paired-year period and for each race-sex group were generated. Nonparametric procedures were used for statistical comparison.[5]

Results

There were no discernible changes in the birthweight distributions especially among Black infants and no statistically significant differences in birthweight distributions between the two time periods for any race-sex comparison (Figures 1 and 2). The shift toward larger infants was more obvious for White infants than for Black infants when comparing categorical values (Table 1). There was no change

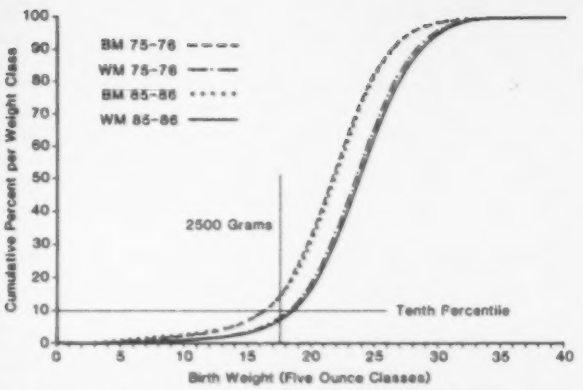

FIGURE 2—Cumulative Birthweight for Black and White Male Infants, South Carolina, 1975–76 vs 1985–86

in the proportion of Black or White infants weighing less than 2500g. Among White female and male infants, increases in birthweight were observed at the 10th, 50th, and 90th percentiles. Increases were observed among Black female infants only at the 90th percentile and among Black male infants only at the 50th percentile.

Changes were observed for certain maternal characteristics related to birthweight and/or infant mortality from 1975 to 1986 (Table 2). The proportion of teenagers giving birth declined from 32 percent to 23 percent among Blacks and from 19 percent to 12 percent among Whites accompanied by an increase in the proportion of women 30 years of age or older giving birth. A 16 percent difference (from 46 percent to 30 percent) in the proportion of mothers with less than a high school education was observed among Blacks with a 10 percent difference observed among Whites (from 31 percent to 21 percent). The proportion of unmarried mothers increased from 43 percent to 53 percent among Black women. There was little change in the proportion of expecting mothers seeking early prenatal care over the 10-year period.

Discussion

It is clear that there has been no real improvement in the proportion of infants weighing less than 2500g between 1975 and 1986. Improvements in birthweight in this period are attributable to the segment of population producing less-than-average weight infants, but not so small as to qualify as low birthweight, i.e., <2500 g. The observations presented here are consistent with other reports showing only overall marginal and selective improvement in birthweights.[3]

Neonatal mortality rates in South Carolina declined by 32 percent among Blacks (from 17.2/1,000 live births to 11.7/1,000 live births) and by 39 percent among Whites (11.4/1,000 live births to 6.9/1,000 live births) from 1975 to

1986. (Office of Vital Records and Public Health Statistics, South Carolina Department of Health and Environmental Control, Columbia, SC.) Clearly the changes in neonatal mortality rates are not explained by changes in birthweight distributions. Low birthweight is an underlying contributor to neonatal mortality intricately related to a host of other biological, medical, sociodemographic, and behavioral factors. While many of these factors are vague, non-specific and non-operational, they are, in turn, related to specific, intervenable factors of prenatal care, nutritional intake, and smoking and alcohol consumption during pregnancy.[6] The explanation for the apparent paradox between significant declines in neonatal mortality rates and very marginal improvement in birthweight is not likely to be found in an examination of medical records and routinely collected vital statistics.

Finally, the absence of improvement in the proportion of low birthweight (LBW) infants over the time period 1975–86 should raise questions about either a flawed strategy of national health policy and/or inadequate application or utilization of support programs such as WIC (Women, Infants and Children supplemental feeding program), AFDC (Aid for Families with Dependent Children), and food stamps. Focusing on infant mortality as both a guide to operations and as a criterion for success in maternal and infant health programs is a suspect strategy. The effect of reducing the proportion of infants in the low birthweight tail of the distribution would certainly result in improvements in infant mortality rates, but not vice-versa. If the evidence of improvement among those whose infants weighing above the 2500g critical value is correctly interpreted, then there is more than a hint that the national strategy as it is applied in South Carolina should look beyond infant mortality. One approach would be to renew attention to conditions of life which are clearly known to influence maternal/familial well-being: hygiene, sanitation, crowding, nutrition, injury hazards, toxic substances, and unsafe conventions of behavior in the home and neighborhood.

Unlicensed Midwifery Practice in Washington State

SUSAN J. MYERS, LM, MPH, PATRICIA A. ST. CLAIR, ScD, STEPHEN S. GLOYD, MD, MPH, PHILIP SALZBERG, PhD, AND JOANNE MYERS-CIECKO

Abstract: We examined the role of unlicensed midwives in Washington State by questioning mothers of infants born out-of-hospital with an unlicensed person in attendance. Only a small proportion of the state's births (0.11 percent) were attended by unlicensed midwives. Unlicensed midwives attended 7 percent of home births, licensed midwives and certified nurse-midwives attended 69 percent. Mothers chose unlicensed midwives because they had religious beliefs in common, or because they were the only providers available who would attend a home birth. (*Am J Public Health* 1990; 80:726–728.)

Introduction

In 1981, the Washington State legislature passed a Midwifery Act which established standards for direct-entry (i.e., without prior nursing) midwifery education and practice. To become a licensed (direct-entry) midwife, the law specifies that applicants be graduates of a state accredited educational program wherein they receive at least three years of coursework and clinical experience. Only a handful of other states license direct-entry midwives. Washington's law is considered unique in the United States because its standards are consistent with those established by the International Confederation of Gynecology and Obstetrics and the International Confederation of Midwives.[1]

The Washington State Midwifery Act permits unlicensed midwives to practice as long as no fees are charged. In a recent review of the Act, the legislature added an amendment to allow unlicensed midwives with documented experience to challenge the licensing examination without completing the required coursework. The amended Act also stipulated that data be provided to determine the role of unlicensed practitioners in the provision of maternity services in the State of Washington. Accordingly, the present study was undertaken to determine the proportion of births that were attended by unlicensed midwives and other unlicensed attendants, and the reasons for mothers' choice of an unlicensed midwife.

Methods

Births which took place out-of-hospital (in a birth center, medical facility, home, or "other" setting) were selected from 1986 birth certificates (N = 1656). Those with an unlicensed person in attendance (mother, father, unlicensed midwife, other or unknown attendant) were identified (N = 423). Records

TABLE 1—Birth Attendant Reported by Respondents Compared with Birth Attendant Recorded on Birth Certificate

Birth Attendant Recorded on Birth Certificate	Birth Attendant Reported by Respondents					
	Physician	Licensed Midwife/ Certified Nurse-Midwife	Father Mother	Unlicensed Midwife	Other	Total
Father/Mother	0	7	26	17	0	50
Unlicensed Midwife	0	9	0	12	1	22
Other/Unknown	47	11	15	38	23	134
Total	47	27	41	67	24	206

were checked by matching attendant's name on the birth certificate against state rosters of licensed providers.

Eight births were excluded because of a missing address or because the birth mother was not the infant's legal guardian. A questionnaire was mailed to the remaining 415 mothers, asking for verification of type of birth attendant and place of birth, whether they had planned an out-of-hospital birth, and the reasons for their choice of birth attendant. Follow-up telephone calls were made to non-respondents for whom telephone numbers could be found. A second questionnaire was sent to those who could not be reached by telephone.

Results

The response rate was 49.6 percent. Compared to respondents, non-respondents were more likely to be teenagers (11 vs 3 percent), other than White race (12 vs 5 percent), and unmarried (26 vs 7 percent). No differences were found in the proportion of mothers living in rural counties or having professional occupations.

The attendant category on the birth certificate agreed with the mother's response in only 30 percent of the cases (Table 1). Sixty-seven respondents said an unlicensed midwife attended their birth but only 12 birth certificates were correctly coded as such; 47 women said their birth attendant was a physician and 27 said the attendant was a licensed or certified nurse-midwife, for a combined total of 74 (36 percent) reporting that their birth attendant was actually licensed.

Table 2 shows the attendants and birthplaces for the 1656 out-of-hospital births with attendant classifications changed to reflect the 206 survey responses. The majority of these births occurred at home. Of the 76 births classified as having an unlicensed midwife attendant, 75 were home births. Of the 1,030 home births, licensed midwives accounted for the

*Mother, Father, Other, Unknown
Source: Washington State Vital Data, 1986, and 206 survey respondents

greatest proportion of attendants; unlicensed midwives attended only 7 percent.

Licensed midwives and certified nurse-midwives were more likely than unlicensed midwives to serve urban, married professionals (Table 3), while unlicensed midwives attended mothers residing in rural counties.

Only 13 percent of respondents said their out-of-hospital birth was unplanned. All such respondents were attended by a mother, father, friend, or other person.

Reasons for the choice of an unlicensed midwife include: "I could not find a licensed birth attendant in my community willing to attend an out-of-hospital birth" (31 percent), and "A major factor in my decision was to have someone to care for me with religious beliefs similar to my own" (31 percent).

Most respondents attended by unlicensed midwives were satisfied with the care they received, although 25 percent reported that they would have preferred a licensed midwife or doctor. Sixty-seven percent said their unlicensed midwife charged a fee for her services.

Discussion

These results suggest that unlicensed midwives attend a small proportion (0.11 percent) of births in Washington State. However, for several reasons, our data may underestimate the true proportion of unlicensed midwife-attended births. If it is assumed that all unlicensed attendants of out-of-hospital births were actually unlicensed midwives, approximately 18 percent of the 1,656 out-of-hospital births would have been attended by unlicensed midwives, 0.43 percent of the state's total births. Even at this upper end of the range of plausible estimates, the proportion of unlicensed midwife-attended births is still quite small.

If the mother's questionnaire response is correct, the extent of attendant misclassification on birth certificates was surprising. Although we expected to find unlicensed midwife attendants concealed within the other unlicensed categories, there were also numerous instances of births attended by licensed providers that had been attributed to unlicensed attendants on the birth certificate. In these cases, birth certificates were either inaccurately completed or coded incorrectly.

Apparently many respondents chose an unlicensed midwife because they were unable to locate a licensed provider who would attend an out-of-hospital birth. This is consistent with the finding that women attended by unlicensed midwives are more likely to reside in rural counties than their counterparts attended by licensed midwives or certified nurse-midwives.

Shared religious beliefs was another reason cited for the choice of birth attendant. It was later learned that some unlicensed midwives regard their practice as a ministry to serve fellow churchwomen.

That two-thirds of mothers attended by unlicensed midwives paid a fee for service suggests that in most cases this was a professional relationship, not simply one friend helping another. Technically, unlicensed midwives who charge a fee are practicing illegally. However, because they are responding to the needs of particular groups of women, they are likely to continue to practice in spite of legal prohibitions. Legislation prohibiting unlicensed midwives from practicing is rarely enforceable.[2] Indeed, the real effect of such legislation has been to force unlicensed midwives to work in secret or to prevent them from seeking education and training.[2,3] Providing an avenue to legal midwifery practice may be a more appropriate course of action so long as competence, equivalent to other licensed providers, can be demonstrated.

Occupational Physical Activity and other Risk Factors for Preterm Birth among US Army Primigravidas

GILBERT RAMIREZ, DRPH, RICHARD M. GRIMES, PHD, JOHN F. ANNEGERS, PHD, BARRY R. DAVIS, MD, PHD, AND CARL H. SLATER, MD

Abstract: We examined the relation of occupational physical activity to the risk of preterm birth among US Army active-duty primigravidas between 1981 and 1984 using 604 cases (preterm deliveries; ≤ 37 weeks gestation) and 6,070 controls (term and post-term deliveries). Women employed in the highest physical activity levels had increased odds of preterm delivery ranging from 1.69 to 1.75. The relation was not changed by adjustment for the effects of age, marital status, socioeconomic status, or education. Missing data suggest cautious interpretation. (*Am J Public Health* 1990; 80:728–729).

Introduction

Relatively few studies have examined the relation between physical activity on the job and the risk of preterm birth, and the findings have been mixed. In a French case-control study, risk of preterm birth was related to the number of sources of occupational fatigue and with a work-week longer than 40 hours.[1] This finding was not confirmed in a case-control study in New Haven, Connecticut;[2] decreased risk of preterm birth was seen among women participating in sports or physical fitness exercises during pregnancy.

The population of US Army active-duty gravidas presents an unusual opportunity to study the relation between preterm birth and occupational physical activity because of its large size and homogeneity, and because US Army military occupational specialties (MOS) had undergone physical demand assessments.

Methods

In 1977, entry level specialties for enlisted personnel were categorized by maximum upper body strength requirements as required for "combat conditions" performance (see Appendix).[3] This physical activity measure was not a specific measure of actual physical activity during pregnancy.

Data for this study were obtained from Patient Administration Systems and Biostatistics Activity, Fort Sam Houston, Texas for length of gestation (from maternal and infant inpatient records) and from US Army Military Personnel Center, Alexandria, Virginia for physical activity and other demographic data (from fiscal year personnel files).

Each subject was assigned to her MOS physical activity level during pregnancy using the fiscal year corresponding to her mid-gestation date. US Army policy forbids the reassignment of women during pregnancy.

The population of US Army active-duty gravidas delivering at US Army medical treatment facilities numbered 22,450 during the four-year period 1981–84. This period was chosen because of differences in coding schema for inpatient records prior to 1981; data for deliveries after 1984 were incomplete at the time of this study. Eligibility criteria for the study sample included primiparity, singleton delivery, and enlisted paygrade status. Officer occupations had not been assessed for physical demand requirements.

Cases were defined as preterm deliveries (≤ 37 weeks gestation); controls included term and post-term deliveries.

Risk factors studied included age, race, pay grade, length of military service, marital status, education, occupational aptitude score, job skill level, and type of military unit. The latter two variables were included to control for the initial focus of the MOS physical demand analysis: "entry level skills in a combat environment." Military duties performed in a field unit closely resemble how they would be performed in a combat environment. The occupational aptitude score was included since it is also used to determine MOS eligibility.

Odds ratios were computed for each separate risk factor. The dose-response relation between occupational physical activity and preterm birth was assessed with the Mantel test for trend.[4] We also fitted a logistic regression model and estimated population attributable risk.[5]

Results

Of the 22,450 US Army active-duty deliveries between 1981–84, 20,584 were to enlisted women. Of these, 20,218 were single live births. Using the mothers' Social Security Numbers (SSN), 12,911 of the 20,218 (64 percent) maternal inpatient records could be matched to infants' inpatient records. Seventy-two percent (9,262) of these matched records met the primiparity criterion. Using the maternal SSN, 7,821 were matched with personnel records. Of these, 1,147 records could not be used due to MOS data entry errors. The remaining sample of 6,674 included 604 cases and 6,070 controls.

Odds ratios for each risk factor are presented in Table 1. Risk factors for preterm birth included the two highest physical activity categories, age less than 20 years, other than White race, pay grades E1 to E3, less than two years' total military service, a never-married status, and an occupational aptitude score less than 100. The level of physical activity was positively related to risk. Condensing the five-category physical demand model to three categories, we found only minor changes in odds ratio estimates and chi-square values by controlling for other risk factors one at a time using a stratified Mantel trend test.*

The analysis of a multifactorial model using logistic regression resulted in three significant predictors of preterm birth: physical activity, race, and military pay grade. The combined risk of a preterm birth for all three factors ranged from 3.3 for those employed in "heavy" physical activity to 3.6 for those employed in "very heavy" physical activity. The population attributable risk for the risk factor occupational physical activity was estimated as 17.5 percent when adjusted for pay grade and race.*

TABLE 1—Estimates of Relative Risk for Preterm Birth

*Missing data

Discussion

The results of this study should be interpreted with caution for several reasons. First, a considerable amount of information was lost when maternal inpatient records were not matched to their infants' inpatient records or their personnel records. Approximately one-fifth of the lost information was from the births occurring in civilian hospitals which do not forward information pertaining to the infant to the nearest military facility. The remaining four-fifths of data were lost because social security numbers did not match. Prior to 1985, there was no uniform policy regarding the entry of social security number on an infant's inpatient record when both parents were active-duty. The impact of the lost information may be small, however, since the dependent variable, length of gestation, and the primary independent variable, physical activity, were obtained from two independent sources, and there is no reason to suspect any systematic bias with regard to these two variables.

A greater concern is that information was not available to this study on potential confounders such as nutrition practices, smoking habits, alcohol consumption, and pregnancy complications.

Other studies have shown activity-duty gravidas to be at high risk for adverse reproductive outcomes, particularly when compared to wives of active duty males.[6,7] Active-duty gravidas are required to continue work until delivery; although military physicians provide recommendations to the pregnant soldier's commander regarding restrictions, these are often general in nature and rarely address physical activity beyond prohibiting participation in regular unit physical fitness programs.

The strength of this study was the consistency of the observed relationship between occupational physical activity and the risk of preterm birth even after controlling for risk factors such as age, race, and socioeconomic status. Additional research in this area seems called for.

Pawtucket Heart Health Program Point-of-Purchase Nutrition Education Program in Supermarkets

MARY K. HUNT, MPH, RD, R. CRAIG LEFEBVRE, PHD, MARY LYNNE HIXSON, MA, RD, STEPHEN W. BANSPACH, PHD, ANNLOUISE R. ASSAF, PHD, AND RICHARD A. CARLETON, MD

Abstract: Point-of-purchase nutrition education in supermarkets is one intervention strategy of the Pawtucket Heart Health Program, a community cardiovascular disease prevention program in Pawtucket, Rhode Island.

Using consumer intercept interviews, awareness of shelf labels and their effect on purchase behavior have been continuously evaluated. Between 1984 and 1988, the percent of shoppers who could identify correct labels increased from 11 percent to 24 percent (95% confidence intervals of difference: 7,17). The percent who reported they were encouraged to purchase the identified foods increased from 36 percent to 54 percent (95% CI of difference: 5,41). (*Am J Public Health* 1990; 80:730–731.)

Introduction

Because 57 percent of the adult population has blood cholesterol levels that put them at moderate or high risk for cardiovascular disease (CVD),[1] many Americans need to change their dietary intake of saturated fat and cholesterol to reduce their blood cholesterol level and CVD risk.

To reach this large number of people, Blackburn and Kottke delineate the need for population strategies.[2,3] The Pawtucket Heart Health Program, a comprehensive community heart disease prevention study,[4–7] developed the "Four Heart Program," a point-of-purchase (POP) nutrition education program in supermarkets and restaurants, as one of its population strategies. We report the results of a study of consumer awareness of the supermarket program and its influence on self-reported purchase behavior.

Methods

The Four Heart supermarket program was started in three supermarkets owned by two different companies and one small family-owned market in 1983–84. The name, Four Heart, represents foods that are tasty and contain less fat, cholesterol, and sodium. The basis of the program is the placement of brand-specific shelf labels next to the unit price tags of qualifying foods. Original multi-colored shelf labels that identified products low in sodium, fat, and/or calories were replaced in 1986 with labels of uniform color with the messages: "low-fat", "low-sodium", "low-fat, low-sodium", and "fat ratio OK." Collateral and support materials include signs with health messages in areas where shelf labels cannot be applied; "Look for the Labels" posters with lucite holders for brochures; free recipe cards; periodic promotions such as contests and blood pressure and cholesterol screening, counseling and referral events (SCORES); and training of store and department managers and of lay volunteers as program monitors.

Criteria used to determine the eligibility of foods for these labels were adapted from the Minnesota Heart Health Program[8] and Food and Drug Administration (FDA) food labeling regulations and recommendations[9,10]

Whereas FDA-sponsored descriptive programs labeled all products in the store that met their nutrient criteria,[11,12] we were interested in studying a more prescriptive program. Only those foods included in meal pattern recommendations based on the US Dietary Guidelines for Americans[13] are labeled.

Consumer intercept interviews were conducted at approximately yearly intervals over four years in two supermarkets from two chains. Interviews were administered in a similar manner across all stores and time periods.

Participants

Individuals exiting a store who were judged to be at least 18 years old were eligible for the interview. Once selected, an individual exiting the store was asked if s/he had purchased something in the store. Those who indicated that they had made a purchase were interviewed.

Procedure

Shoppers were selected for interviews based on a time sampling procedure. Using a stop watch, the interviewer selected a potential respondent by approaching the first age-eligible shopper to exit the store at five-minute intervals.

Instrument

Data on frequency of shopping were obtained. To assess awareness of shelf labels, a placard containing four sets of labels, three of which were bogus sets, was shown to the respondent. The shopper was asked if s/he saw any of these labels inside the store. If the answer was yes, s/he was asked to identify the set seen. Those shoppers who reported seeing the labels actually on the shelves were counted to assess the influence of the labels on purchase behavior.

Results

Awareness of Labeled Items

Interviews with 1,807 shoppers were conducted over the four-year period. Fifteen percent more shoppers reported seeing any labels on the store shelves between 1984 to 1988 (Table 1).

Awareness was related to gender; 32 percent of female shoppers versus 24 percent of male shoppers reported seeing one of the labels shown to them (95% CI = 4,12). Thirteen percent more shoppers were able to identify the correct label between 1984 and 1988 (Table 1). Female shoppers identified the correct labels 23 percent of the time compared with 12 percent for males (95% CI = 7,15).

Influence of Shelf Labels on Purchase Behavior

Encouragement to purchase labeled foods was reported more frequently in 1988 than in 1984 among shoppers who correctly identified Four Heart labels (Table 1). Encouragement to purchase labeled products did not differ appreciably between male and female shoppers.

TABLE 1—Consumer Awareness and Effect of Food Product Shelf Labeling

	Total Surveyed	Yes[a]	Correct[b] Label	Encouraged[c] Purchase

[b] Shoppers correctly identifying the "4-Heart labels" of total surveyed
[c] Shoppers stating that label encouraged purchase of those who saw correct label

Discussion

The supermarket program reached large numbers of people with low fat, low sodium eating pattern messages over a four-year period of time. In order to quantify this reach, we applied findings from our study to industry averages obtained from the Food Marketing Institute, Washington, DC (personal communication). In 1987, the mean weekly store sales in US supermarkets was $184,210 with an average transaction of $16.30. This translates to 11,301 transactions per store per week.

Based on our interviews, customers shopped an average of 2.3 times a week. Therefore, we estimate that the participating supermarkets served 4,913 customers a week.

Projecting our findings from these averages, by 1988 each week an estimated 1,179 customers recognized Four-Heart shelf labels while shopping and 636 of them were encouraged to purchase labeled products. It would be difficult and expensive to achieve this exposure to health messages and change in purchase behavior with one-to-one or small group methods of nutrition education.

Although a larger percentage of females than males identified the correct labels, approximately one-half of both males and females reported that they were encouraged to purchase the labeled foods. This is of particular interest because males have lower participation rates in traditional nutrition education programs than females[14,15] and are at higher risk for CVD—one in three will have clinical signs of CVD before the age of 60.[16]

Two important caveats must be given to these results. The first is that this program evaluation occurred within the context of a large, broad-based intervention effort to raise awareness of, and stimulate changes in, CVD risk behaviors. Secondly, other secular trends such as the increasing media coverage of cholesterol-related topics, and the efforts of the National Cholesterol Education Program and American Heart Association in this area, may also have added to the observed increases.

Yet, our data do support the findings of other studies which have demonstrated that point of purchase nutrition education in supermarkets is feasible and effective in increasing consumer awareness of nutrition messages over time[11,17,18] and in exerting a positive influence on self-reported purchase behavior.[18] Because of the ambiguous results of studies of actual consumer purchase behavior,[11,12,17,19–22] further controlled studies of this intervention in supermarkets need to be undertaken.

Infant Feeding Practices: An Evaluation of the Impact of a Health Education Course

ILANA SHOHAM-YAKUBOVICH, MPH, PHD, JOSEPH S. PLISKIN, PHD, AND DANIEL CARR, MS

Abstract: We assessed the impact of a health education course on infant feeding practices in the West Bank territories by comparing mothers who had attended the course (n = 102) with mothers not exposed to the course (n = 133). After adjustment for child's age, maternal age and education, parity, and birth site, course participants were more likely than non-participants to breastfeed, as well as to start supplementation by semi-solid foods at the recommended time. (*Am J Public Health* 1990; 80:732–733.)

Introduction

A comprehensive project of health education for mothers of young children in the villages of the West Bank territories, a population of low socioeconomic status, was designed as part of a food distribution activity.[1,2] Prior assessment of needs and problems of the local population indicated that a growing number of the mothers wean their children too soon, and introduce semi-solid foods either too early or too late. One of the main objectives of the course was to change these feeding practices. The course was taught in small groups by specially trained local instructors who adapted teaching materials developed for the course to the specific questions and issues raised by their groups. The course focused on nutrition, hygiene, child development, and first aid. The process of course development, design, methods, and content were described elsewhere.[1,2]

From 1985 to 1987, the program offered 972 courses in 152 villages (about one-third of the 443 villages in the West Bank) and in five cities throughout the West Bank. Participation of villages in the program was voluntary. In participating villages, most mothers of young children joined the course. Participating mothers received a small supply of basic food commodities. Overall, 19,984 mothers participated in these courses.

The present paper assesses the impact of the course on infant feeding practices, by comparing a sample of mothers who had attended the health education classes with a sample of mothers who had not been exposed to the course.

Methods

A survey was conducted in 92 villages throughout the West Bank, 46 which participated in the program, and 46 which had not participated. The sample of villages was randomly selected in proportion to the population distribution in six districts. Approximately six mothers in each village were interviewed. In experimental villages, the respondents were randomly selected from the list of course participants. In the comparison villages, respondents were selected in most cases from among the mothers whose children were attending school at the time of the survey. Structured interviews were conducted between August and December 1987 by female field workers experienced in village habits and familiar with local customs and culture. The present analysis includes 235 mothers whose youngest child was one year or less. Of these, 102 attended the course and 133 mothers did not attend the course. Statistical analysis

includes comparisons of crude and age-adjusted proportions. Confidence intervals (CI) for differences of crude and standardized proportions were calculated by methods suggested by Rothman.[3] Mantel-Haenszel chi square was used to assess statistical significance of stratified analysis.[4] Multivariate logistic regression was performed to assess the effect of the health education course on feeding practices, controlling for other variables.[3]

Results

There were no differences of consequence in maternal age, number of children, and maternal level of formal education between the two groups (Table 1), but 51.1 percent of the course participants delivered at home assisted by a local midwife (Daya) or by a female relative, while only 35 percent in the comparison group delivered at home. All other women delivered in a clinic or a hospital.

Proportions of breastfeeding mothers were higher in the course group than in the comparison group, irrespective of child's age (Table 2). Introduction of semi-solid foods at 4–6 months (the recommended pattern) was more prevalent in the course group than in the comparison group (76 and 57 percent, respectively; 95 percent CI for the 19 percent difference = 7.1–30.9). Starting semi-solid foods at age 6 months was a more common practice in the comparison group than in the course group (16 and 1 percent, respectively).

Women who gave birth at home were more likely to start breastfeeding than women delivering in the hospital (97 vs. 74 percent), and to be still breastfeeding at 10–12 months (58 percent vs. 42 percent). Comparing rates of breastfeeders (adjusted for child's age) demonstrates that course participants were more likely to breastfeed, regardless of site of delivery (home vs. hospital or clinic). The difference, however, significantly exceeds 0 only among mothers delivering in the hospital (Table 3).

After controlling for child's age, site of delivery, maternal age, level of education, and parity, course participation continued to be associated with breastfeeding at the time of interview, as well as with starting supplementation with semi-solid foods at age 4 months (Table 4). Breastfeeding was also associated with child's age and home birth. The recommended pattern of supplementation with semi-solid foods, was associated with course participation, maternal education, and number of children (Table 4).

Discussion

The pattern of findings is consistent with the conclusion that the course was successful in influencing mothers' feeding habits. The results, however, could have been influenced by several biases inherent in the study design. Since our study is cross-sectional, and since the course was not randomly assigned, it is possible that health education project villages differed from the comparison villages in aspects relevant to child feeding practices for which no information was available. However, stratification on site of last delivery and multivariate adjustment for maternal age and education, site of delivery, number of children, and child's age suggest that course participation had a unique contribution to feeding behavior.

Another possibility is that women in the health education group report, but do not behave, differently than the comparison group. Even if some reporting bias does exist, the mere knowledge in itself about appropriate practices is a

worthwhile benefit of the course.

Our findings are consistent with a previous study showing a beneficial effect of special class on breastfeeding among mothers of low socioeconomic status.[5] These findings are encouraging in light of the trend observed among mothers of low socioeconomic groups,[6,7] and mothers in third world countries of declining rates of breastfeeding.[8]

Pertussis Immunization in Eight-Month-Old Children in North Carolina

DENNIS A. CLEMENTS, MD, MPH, CATHERINE M. WILFERT, MD, J. NEWTON MACCORMACK, MD, MPH, KRISTEN A. WEIGLE, MD, MPH, AND FLOYD W. DENNY, MD

Abstract: Between 1984 and 1987 reported pertussis cases in North Carolina increased threefold. Pertussis immunization rates were examined for those years in three one-year cohorts drawn from a random selection of North Carolina birth records. The percentage of children immunized with three DTPs at eight months of age was 58.1, 58.6, and 56.7 for the three cohorts. Only 20.5 percent of 117 reported pertussis cases in children 9–36 months of age during the last 10 years were adequately immunized. The low pertussis immunization rate may have contributed to the recent increase in pertussis cases in North Carolina. (*Am J Public Health* 1990; 80:734–735.)

Introduction

The United States has reported a recent increase in the number of pertussis cases.[1,2] In North Carolina the annual average of reported pertussis cases increased from 40 for the 10-year period 1975–85 to 88 and 123 cases in 1986 and 1987 respectively.

Although it is estimated that over 95 percent of North Carolina children entering primary school have the pertussis immunizations required recently by state law, a 1980 sample survey in North Carolina estimated that only 66 percent of two-year olds had received the recommended four DTP (diphtheria/tetanus/pertussis) injections.[3] Even less is known about the immunization status of children under one year of age who are at the greatest risk of severe pertussis disease and account for the majority of the cases reported and hospitalized.[4]

Our study was designed to examine the immunization status of eight-month old children in North Carolina during the time period 1984 to 1987, immediately preceding and during the pertussis epidemic.

Methods

A systematic random sample of 600 birth records was selected from all recorded North Carolina births between May 1, 1984 and April 30, 1985. Information on DTP immunization status was obtained using mailed questionnaires; with telephone or health department record follow-up for non-responders. From each of two birth cohorts: 5/1/85–4/30/86 and 5/1/86–4/30/87, 327 birth records were similarly selected. A 10 percent random sample was selected from those not responding for telephone interview. The telephone information was extrapolated to represent a similar fraction of the entire nonresponder group in each cohort to give an adjusted immunization rate.[5]

A child was considered properly immunized if three DTP injections were received by 244 days (eight months) of life. A few extra weeks beyond the recommended age (six months of age) for the third DTP immunization was allowed to avoid depressing the primary series completion rate by those who were only minimally delayed in obtaining immunization.

Confidence intervals for proportions were calculated using the normal approximation to the binomial distribution when n was sufficiently large. Hypothesis tests were performed using the normal approximation to the binomial for proportions, chi-square test statistic, Fisher's exact test or chi-square test for trend as appropriate.[6,7]

Results

The response rate in the 1985/86 and 1986/87 cohorts (41 percent and 49 percent, respectively) were lower than the response rate in the 1984–85 cohort (70 percent). Data were obtained by telephone from 44.4 percent of the 1985/86 and from 61.9 percent of the 1986/87 subsamples of nonresponders and used to adjust the final rates.

The adjusted immunization rates were similar for the three study years; 58.1 percent (1984/85), 58.6 percent (1985/86), and 56.7 percent (1986/87) (chi-square test for linear

trend p = .737). Racial characteristics of the adjusted cohorts were similar to those of North Carolina in 1985 and did not play a role in the differences between cohort groups. There were significant differences, however, between the immunization rates for White (1984/85 63.2 percent, 1985/87 62.7 percent) and Black (1984/85 48.3 percent, 1985/87 39.9 percent) children in the adjusted rates.

There were 505 cases of pertussis reported in North Carolina between 1978–87, 350 (69.3 percent) were children less than one year of age (Table 1), the majority occurring in children less than nine months of age (Figure 1). Table 1 shows the immunization rates for the cases by age; 20.5 percent of children aged 9–35 months of age between 1978–87 and 21.4 percent of children for the years 1986/87 were adequately immunized. The median age of cases from 1978 to 1986 was five months and the median age for cases in 1986/87 was seven months.

Extrapolation from the World Health Organization (WHO) nomogram[8] for percent of cases vaccinated and vaccine efficacy (estimated to be 80 percent) gives a population vaccination rate of 55–60 percent.

Discussion

The DTP immunization rates for young North Carolina children as determined in this study were disturbingly low between 1984 and 1987, but remained constant over the three-year period. Therefore, our findings do not substantiate a decreasing rate of pertussis immunization during the study period. Due to the poor response rate, however, particularly in the 1985/87 cohorts, an undetected immunization rate change may exist. The finding that nonresponders located were less well immunized than the initial responders suggests that the rate of pertussis immunization may have been closer to 50 percent if all nonresponders had been contacted.

The recent increase in reported pertussis cases may be due to causes other than failure to immunize. Increased case reporting alone is unlikely because the number of children under one year of age with pertussis requiring admission to major hospitals in North Carolina also increased during 1986/87. The fact that over 40 percent of the reported cases of pertussis were under five months of age also suggests that the low immunization rate in young children was not the sole cause of the increasing incidence of pertussis. However, inadequate immunization of preschool-aged siblings could increase the chance of transmission to young infants. Immunizations are required to be up-to-date when children enroll

TABLE 1—Immunization Status of Reported Pertussis Cases in North Carolina 1978–87

Age at Disease (months)	# DTPs Required	# Immunized	%
<2	0	NA/48	NA
2–4	1	53/161	32.9
5–8	2	27/113	23.9
9–21	3	18/84	21.4
22–36	4	6/33	18.2
37–72	4	11/16	68.8
>72	5	21/50	43.8
TOTAL		136/505	26.9

NA = not applicable. If the 48 children in this group are removed from the denominator because they probably would not have been immunized, the overall immunization rate in the total group would be 136/457, 29.8 percent.

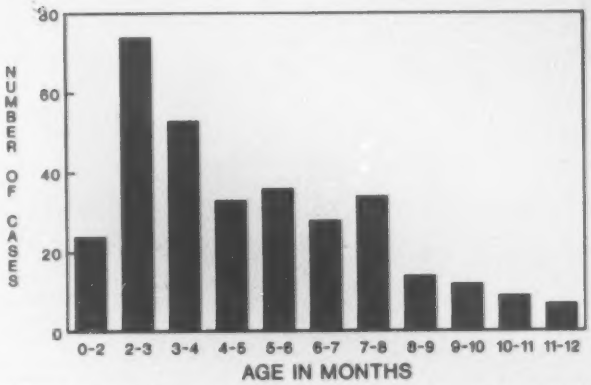

FIGURE 1—North Carolina Pertussis Cases Less than One Year of Age, 1978–87

at certified day care centers in North Carolina but continued updating of records is not normally required and may not be performed. A gradually cumulative increase in this pool of preschool-aged susceptibles could have propagated transmission to younger children during this epidemic.

Bass[1] has suggested that part of the reason for the recent increase in reported pertussis cases in the United States is that there is an increasing proportion of the population that is vaccine-immune to pertussis which is gradually losing its immunity. If older children and adults acquire asymptomatic infection, they could be a source of infection for others not yet immune, particularly unimmunized young children. It is of interest that the median age of pertussis cases increased from five months to seven months after 1985, coincident with the increase in the number of pertussis cases. It is also possible that an increasing use of day care facilities provided increased opportunities for incompletely immune children to be exposed to asymptomatically infected children and adults.

The increase in the number of pertussis cases and the delay in immunization that this and other studies[9] document is cause for concern. The disparity between the immunization rate of White and Black children is also of concern. It is likely, however, that race is a surrogate for socioeconomic status.

The task now is to better define groups of children that are poorly immunized, evaluate the barriers that prevent timely immunization, and formulate appropriate interventions.

Loss of Maternally Acquired Measles Antibodies in Well-Nourished Infants and Response to Measles Vaccination, Peru

ABRAHAM VAISBERG, PHD, JOSE O. ALVAREZ, PHD, HERMINIO HERNANDEZ, MD, DANIEL GUILLEN, MD, PABLO CHU, BS, AND ANA COLAROSSI, MS

Abstract: Clinical, anthropometric, and serological evaluations were conducted at birth and at 3, 6, 9, and 10 months (post measles vaccination) in 34 well-nourished Peruvian infants. Seroconversion rate after measles vaccination was 94 percent. The rate of antibody loss was a direct function of birth titer; at age 9 months, all children had identical mean titers regardless of their titer at birth. Differences in maternally acquired measles antibodies at birth were important only during the first six months of life. (*Am J Public Health* 1990; 80:736–738.)

Introduction

Infants in developing countries become susceptible to measles infection at younger ages than do infants in the industrialized nations.[1–3] Seroconversion rates after measles vaccination among infants younger than 9 months of age in Africa and Latin America are higher than in US infants of the same age.[4,5] Thus, maternally acquired antibodies against measles do not appear to confer the same length of protection in third world infants as in infants from developed countries.

It has been proposed that a lower maternal level of antibody, hence a lower circulating level in the newborn, may be responsible for the early susceptibility to measles infection in infants from low-income regions.[6] Alternatively, Halsey, *et al*,[7] have suggested that third world infants may have an increased rate of measles antibody loss. Elucidation of the reasons for early susceptibility to measles may allow design of more appropriate vaccination schedules.

Methods

The investigation was conducted in San Martin de Porres, a poor district of the city of Lima, Peru. One hundred full term, normal birthweight infants born at Cayetano Heredia Hospital were included in this longitudinal study at the time of birth. The parents agreed to participate in this investigation and brought their children to the hospital for evaluations every three months. Children were examined by a physician at birth and at 3, 6, 9, and 10 months of age. At every visit, mothers were interviewed to assess past infection with measles and other major illnesses. At age 9 months, all participating children were vaccinated against measles and one month later their response to the vaccine was assessed.

Weight and height measurements were made at each visit. Weight for age, weight for length, and length for age were calculated using the National Center for Health Statistics and Waterlow's classification.[8,9]

A venous blood sample was obtained from the mothers at the time of delivery. A small blood sample was obtained from each child at the time of recruitment and at each visit. The last sample (at 10 months) was used to assess seroconversion to measles vaccination. All samples were frozen at −70 °C until processed together.

Circulating IgG specific against measles was measured by ELISA using measles-infected Vero cells and peroxidase-conjugated rabbit immunoglobulin to human IgG according to the method originally described by Rice, Casali and Oldstone.[10] Each serum was diluted serially in saline containing 10 percent fetal bovine serum and 0.05 percent Tween 20 and aliquots of each dilution were assayed. Absorbance was read using a manual EIA plate reader. Positive and negative control sera were included in each assay plate. Also, negative control wells using uninfected Vero cells were included in all assay plates. Absorbance was plotted against log of serum dilution. Using linear regression, the intercept with the abcisa was determined and this dilution value, at zero absorbance, was taken to be the titer.

Attenuated live measles virus vaccine (Connaught, manufactured in Canada) was obtained from the Ministry of Health of Peru and stored at 4C. Each dose contained not less than 1,000 TCID50 of measles virus.

Results

Thirty-four subjects, 17 boys and 17 girls, completed the study and only the samples corresponding to these infants were processed. The nutritional status of the children was normal throughout the study with the exception of three girls who showed mild wasting at 3 months of age but recuperated quickly.

Table 1 shows the mean circulating measles antibody titers for mothers and infants at birth and at 3, 6, and 9 months of age and at post vaccination (10 months of age).

In order to follow the decline of maternally acquired measles antibody, infants were grouped into high, intermediate, and low birth titer. Mean levels of measles antibody were plotted as a function of age for the three groups of infants as shown in Figure 1. Infants with higher birth titers

The break in the lines indicates that the points to the right of the break correspond to the scale on the right ordinate. Open circles (○) correspond to the group of infants with a high birth titer; open squares (□) to infants with intermediate birth titer; open triangles (△) to infants with low birth titer.

lost their antibodies more rapidly than infants with lower birth titers.

The half-life of maternally acquired measles antibody, calculated as described by Lennon and Black,[11] is shown in Table 2. The mean half-life for the three groups of infants was inversely related to birth antibody titer.

Seroconversion rate after measles vaccination was 94 percent among these children. Due to the method used to calculate antibody titer that led to a high sensitivity for our ELISA assay, seroconversion was arbitrarily defined as a post-vaccination titer above 1,000 and at least an order of magnitude higher than the prevaccination value.

TABLE 2—Half-life of Maternally Acquired Measles Antibody for Infants grouped into Low, Intermediate, and High Birth Titer

Group	n	Birth Titer [†]	Half-life (days)[*]	Post-Vaccination Titer

Discussion

Our results show that during the first three to six months of life, infants born with higher levels of measles antibody are better protected against the disease than infants born with lower titers. After 6 months of age this difference becomes tenuous and disappears completely by age 9 months.

Our results are in agreement with several studies that have suggested that the rate of degradation of circulating antibodies depends on the total IgG concentration.[12,13] This phenomenon has been reported in mice,[14,15] rabbits,[16] and human beings.[17–19] The half-life of passively administered gammaglobulin in children with agammaglobulinemia was 50–60 days whereas, in normal children, it was 20–40 days.[20] Cloonan, Hawkes and Stevens[21] have reported that babies having high rubella titers at birth lose their antibody rapidly, whereas in babies with low birth titers, antibody declines over a longer period of time.

The antibody half-life estimate from our data, 56.3 days, is similar to that calculated by Black, *et al*,[6] for Taiwanese children (53.3 days) but longer than that observed in children from Kenya (46.8 days).[22]

It is interesting to note that boys showed higher antibody titers than girls at all ages, although this may not hold up with larger samples.

Black, *et al*.[6] have used maternal and cord measles data from 15 populations from nine countries to demonstrate a strong inverse correlation between per capita income and the age at which children respond to measles vaccination. The authors have observed also a correlation between maternal antibody titer and the age at which children seroconverted. These findings led them to postulate that children in developing countries become susceptible to measles infection at an earlier age than children in industrialized countries because they receive less antibodies from their mothers.

Our study, even though it involved a small number of healthy and well-nourished children, suggests that infants appear to have equal protection after eight months of age regardless of what their antibody level was at birth. The fact that no correlation was observed between infant titer at birth and post vaccination titer strengthens the validity of our findings. If the length of protection conferred by maternal antibody as suggested by Black, *et al*,[6] were primarily a consequence of infant titer at birth, one would expect vaccination titer to be an inverse function of birth titer. This was not the case in our study. Other factors are probably involved in the early loss of passive measles immunity in children from developing countries.

The Prime Time Diet: A Content Analysis of Eating Behavior and Food Messages in Television Program Content and Commercials

MARY STORY, PHD, RD, AND PATRICIA FAULKNER, MS

Abstract: The purpose of this study was to identify and analyze messages related to food and eating behavior as presented on prime time television (8:00–11:00 pm) both in programming and commercials. Food references occurred an average of 4.8 times per 30 minutes of programming time. Over half (60 percent) of all food references in programs were for low nutrient beverages and sweets. The prime time diet is inconsistent with dietary guidelines for healthy Americans. (*Am J Public Health* 1990; 80:738–740.)

Introduction

The American population spends more time watching television than it spends in any other activity except sleep and work.[1] There is increasing concern about the impact of this powerful and pervasive medium on health and health-related behaviors.[1–6] While the exact nature of the impact of television on behavior is controversial and largely unstudied, there is no doubt that many health-related images and messages are constantly conveyed to viewers, and may influence health behaviors. Because of the accumulating knowledge of the relationship of diet to health and chronic diseases, we thought it would be interesting to see how food and eating behaviors are portrayed on television, and whether these messages and behaviors are consistent with dietary recommendations for good health. The purpose of our study was to identify television messages related to food and eating behaviors both in programs and in commercials. Prime time television (8:00–11:00 pm) was selected for content analysis because it attracts the largest viewing audience among all age groups, with the exception of preschoolers.

Methods

The 1988 Nielsen Report on Television[7] was used to select the top nationally ranked prime time evening network programs for analysis. From the 15 top ranked shows among total US television households, only those featuring dramatic or situational comedy series were selected for analysis. Eleven programs were analyzed: the Bill Cosby Show; A Different World; Cheers; Growing Pains; Who's The Boss; Murder She Wrote; Golden Girls; L.A. Law; Moonlighting; Family Ties; and Alf.

Each program was video taped on two separate occasions during a nine-week period in the summer of 1988. A trained assistant viewed each video tape and coded all references to food and all eating occasions in programs and

commercials on an instrument adapted from one developed by Kaufman.[8] The coding was checked for reliability by double coding a subsample of programs by an independent observer. For each reference to food or drink in programming, the coder identified the food or drink involved, whether it was a verbal or visual reference, or an actual eating scene, and the context in which food was eaten (meal or snack). Incidental visual references to food (e.g., a basket of fresh fruit on a kitchen counter) were counted as food references. Verbal references using food in a figurative sense, such as referring to someone as "the big cheese" were not included. All commercials aired during the show were recorded but only those advertising food or beverages were analyzed. The following information was coded: the product name and company, any explicitly expressed messages or claims about the food being advertised, and food shown other than that being advertised.

Results

Food references in prime time shows (excluding commercials) occurred an average of 4.8 times per 30 minutes of programming time (134 food references). References to low nutrient beverages (coffee, alcohol, soft drinks) occurred at a higher rate than any other category of food (Table 1). Over half (60 percent) of all food references in prime time programs were for low nutrient beverages and sweets.

TABLE 1—Rates of Occurrences of References to Food in Television Programs by Food Category*

Food Category	Total References (n)	Rate (per Half Hour)

Condiments	2	0.07	0.01

*A total of 28 half-hour segments were viewed.

In the 22 shows, there were 86 occasions of eating or drinking. Almost three-fourths (72 percent) of the food eaten on prime time shows is eaten between meals. Snacking occurred at a rate of 2.2 times per half hour of programming versus .86 times for meals. The most frequent snack food was sweets (44 percent), followed by salty snack foods (25 percent). Less than 10 percent of snacks were fruits (3 percent) or vegetables (6 percent). Coffee (43 percent) was the most frequently consumed beverage, followed by alcohol (28 percent) and soft drinks (17 percent).

Of the 24 episodes involving meals, 12 were evening meals and six were breakfast and six lunch. Breakfast foods consisted of either cereal and toast (50 percent) or sweet rolls and donuts (50 percent). Fruit was shown three times at breakfast and once at lunch. In almost one-third (33 percent) of the noon and evening meal episodes, the only food portrayed was dessert (with either coffee or wine). Other foods shown for these meals were sandwiches (28 percent); salads (11 percent); entrees (28 percent), consisting of stir fry vegetables and chicken which the children refused to eat; lobster with butter; hot dogs and veal with potatoes. One-third of all meal episodes included alcohol.

Of the 261 commercials aired, 91 (35 percent) were food ads. Table 2 shows the number and rate of food references in commercials by food category. Commercials for fast food restaurants occurred at a higher rate than any other food category. The fast foods advertised were hamburgers, fried chicken, pizza, and breakfast sandwiches. None of these commercials advertised salads or salad bars. Only three commercials advertised fruit, and none advertised vegetables; however, fruits and vegetables were incidentally shown in 36 percent of all food ads (e.g., orange juice in an ad for breakfast cereals; fruit shown in an ad for candy).

The most frequently expressed message in commercials were claims of "good taste" and food being "fresh and natural." Few commercials made explicit nutritional claims. Those that did tended to be ads for unsweetened breakfast cereals, claiming that the products were nutritious, low in fat and sodium, and high in fiber.

Discussion

References to food were pervasive, both in prime time programs and in accompanying commercials. The "prime time diet" primarily consisted of foods low in nutritional quality, such as low nutrient beverages, sweets, and salty snack foods. Foods were typically consumed as snacks rather than meals. This reflects the eating pattern of the American population: diets high in sugar, sodium, and fat and low in fruits, vegetables, and fiber.[9–12] Recent data,[13,14] also indicate that both adults and children are snacking more frequently, and that families are eating fewer meals together. In light of the scientific evidence on the relationship of dietary factors to health and chronic disease risk, several studies, as well as numerous national reports and papers, have pointed to the wide-spread need for public education and changes in dietary behavior.[9–12,15]

Given our findings that messages related to eating practices are conveyed frequently during prime time television viewing, and that the television diet exemplifies poor nutritional practices, an important but unanswered question is whether television exposure to food references has any impact on actual eating behavior. Modeling and social learning theory would suggest that frequent, regular TV exposure might influence eating habits. However, this is speculative and further research is needed.

We believe media can be important in creating social norms and promoting healthy eating practices. Much of the eating on TV programs is trivial and incidental, used for "stage business," that is something to do with one's hands. Although producers, writers, and directors are in the business of delivering entertainment, and not with projecting health images, there is an opportunity to present health promoting messages by having characters model good dietary practices. Health professionals should initiate and work with the TV industry to encourage the inclusion of healthy eating patterns in programming.

Hall, Director of Communications, Office of Medical Applications of Research, National Institutes of Health, Building 1, Room 259, Bethesda, MD 20892. Tel: 301/496-1143.

Seat Belt Use on Interstate Highways

JoAnn K. Wells, BA, Allan F. Williams, PhD, Adrian K. Lund, PhD

Abstract: More than 5,000 miles of limited-access highways in the eastern United States and Canada were traveled to observe seat belt use. Overall belt use was 58 percent in the United States and 79 percent in Canada. The data indicate that belt use in the United States follows a different pattern on interstate highways than on other streets and roads, with relatively high belt use rates (over 50 percent) appearing to be somewhat independent of belt use law provisions. (*Am J Public Health* 1990; 80:740–742.)

Introduction

Information on seat belt use is typically based on observations of motorists on city streets. For example, the National Highway Traffic Safety Administration (NHTSA) has surveyed belt use in 19 major cities annually since 1975.[1] However, belt use is known to vary according to where observations are made, and one location where belt use typically is higher than on city streets is interstate highways. In surveys in four states, belt use was 10–20 percentage points higher on interstate highways connecting the cities than in the cities.[2] Systematic information on seat belt use in vehicles traveling outside cities is lacking. In the four-state study it was collected incidentally as observation teams traveled between cities.[2] The present study provides information on belt use on interstate highways in the eastern United States and compares use rates in states and Canadian provinces with and without belt use laws.

Methods

Seat belt use observations were made by trained observers sitting behind the driver of a passenger van that traveled slower than the prevailing traffic in the far right lane. From that location, observers could clearly see shoulder belt use of front seat occupants of cars, light trucks, and vans passing in the adjacent lane. Lap belt use was not observed. Most cars on the road (all vehicles beginning with model year 1974) have integral lap/shoulder belts in the driver and right front seating positions. However, pre-1974 cars were not excluded so belt use is slightly underestimated.

Belt use observations were made on 5,129 miles of interstate highways in 21 eastern states and on limited-access highways in two eastern Canadian provinces from 9 am to 4 pm weekdays in August 1988. Appendix I provides information on the jurisdictions and highways surveyed and belt use law status.

It should be noted that the kinds of travel on these highways can vary tremendously from state to state. For example, in New York state, I-95 is entirely urban with short distances between access points and large volumes of local traffic; in South Carolina the same interstate is entirely rural with relatively long distances between access points.

© 1990 American Journal of Public Health 0090-0036/90$1.50

Observed differences in belt use for different populations were tested by χ^2 test of independence; only differences $\alpha = 0.05$ are reported.

Results

Seat belt use by the 14,354 front seat occupants observed on the highways surveyed averaged 58 percent in the United States and 79 percent in Canada. Belt use ranged from 48 percent to 66 percent in the 21 states and was 76 percent in Ontario and 84 percent in Quebec (Table 1). In the United States use was higher in states with laws (60 percent) than states without laws (56 percent), but the range of use rates for states with and without laws overlapped considerably. There was no significant difference in belt use between states with laws permitting primary and secondary enforcement.

The majority of occupants (57 percent) were in vehicles registered in the state or province in which they were observed. Of those traveling in out-of-state vehicles, motorists from jurisdictions with seat belt laws were more likely to use belts than motorists from non-law jurisdictions, whether observed in states with laws (66 vs 57 percent), provinces with laws (81 vs 74 percent), or non-law states (66 vs 56 percent).

Belt use was higher among drivers; in cars, utility vehicles, and passenger vans; among those estimated to be age 25 or older; and among women (Table 2).

Discussion

Belt use on interstates is higher than belt use in cities in the same state. Even in states without laws, belt use on interstates was greater than 50 percent, about 20 percentage

*The following passenger vehicles in this category are: Nissan Van, Toyota Van, Mazda MPV, Chevrolet Astro, GMC Safari, Ford Aerostar, Dodge Caravan, Dodge Grand Caravan, Plymouth Voyager, Plymouth Grand Voyager, and Mitsubishi Van. The majority of these vans are sold as passenger vehicles, but the current data include observations of cargo versions as well.

points higher than in cities in these same states surveyed by NHTSA.[1] The laws do make a difference, however, not only in elevating use rates within the states, but motorists with vehicles registered in states with laws are more likely than motorists registered in states without laws to use seat belts wherever they travel. Nevertheless, variations in belt use laws affected belt use less on interstates than such laws are known to do on other highways, i.e., city-based surveys have found belt use to be higher in states with primary enforcement laws.[1,3] This should not be seen as an indication that belt use law differences are unimportant but that there is a different, and higher, pattern of belt use on interstates.

The reasons for higher interstate belt use are not clear. The population of motorists on interstates may be different than on other roads; for example, on average they may be of higher socioeconomic status, which is strongly related to belt use.[4] Also, people often claim in surveys that they are more likely to buckle up for long trips on high speed highways, although no observational studies have adequately tested this claim.[5]

Use rates are high both in Canadian provinces in general and on their limited-access highways.[6] Belt use in Canada was less than 50 percent in the 1970s.[7] Extensive use of programs combining publicity and enforcement during the past decade is thought largely responsible for Canada's present high belt use.[8,9] Such programs have been run successfully on a limited basis in the United States but have not been used extensively enough to increase overall belt use.[10,11]

Ciprofloxacin-Resistant Methicillin-Resistant *Staphylococcus aureus* in New York Health Care Facilities, 1988

LAWRENCE D. BUDNICK, MD, MPH, SAM SCHAEFLER, PHD, AND THE NEW YORK MRSA STUDY GROUP*

Abstract: The emergence in 1988 of ciprofloxacin-resistant methicillin-resistant *Staphylococcus aureus* (MRSA) in New York City was studied in nine hospitals and eight nursing homes. Of the 43 hospitalized patients studied, 21 were admitted from home, while nine of the 12 nursing home patients were transferred from a hospital. Twenty-four of the 55 patients had been treated previously with ciprofloxacin, and 26 had an identifiable risk factor for a nosocomial infection. MRSA was a contributing factor in at least five of the 21 deaths. MRSA resistance to ciprofloxacin was detected within three months of the drug's commercial availability, apparently emerged independently at a number of the health care facilities, and has become widespread. If such resistance is found in a health care facility, ciprofloxacin may not be useful as a first line antibiotic. (*Am J Public Health* 1990; 80:810–813.)

Introduction

Staphylococcus aureus caused a pandemic of nosocomial infections in the 1950s.[1] Shortly after methicillin was introduced into clinical practice, methicillin-resistant *S. aureus* (MRSA) emerged as a prominent cause of nosocomial infections first in Europe and later in the United States.[2–7] Patients can introduce MRSA into a health care facility from the community and cause intra- and inter-institutional spread.[8–11] Ciprofloxacin, an oral fluoroquinolone antibiotic that became commercially available on October 22, 1987, has bacteriocidal activity *in vitro* against MRSA[12] and is reportedly useful for the treatment of infections with susceptible staphylococci of the skin and skin structures,[13] for which it is marketed, bones,[14] and the lower respiratory tract.[15] This report examines the emergence of MRSA resistant to ciprofloxacin in New York City hospitals and nursing homes in 1988.

Methods

The Bureau of Laboratories Phage Typing Unit of the New York City Department of Health is the reference laboratory in New York City for bacteriophage typing of *S. aureus* isolates voluntarily submitted by hospitals, nursing homes, and other laboratories. All facilities do not submit isolates for typing and individual facilities do not necessarily submit all their isolates. The method of phage typing has been previously described in detail.[16–18] In summary, isolates are initially tested for phage susceptibility using the international set of *S. aureus* phages (at routine or 100X routine test dilution concentration) and then are tested using an experimental set of phages (at 100X routine test dilution). In addition, isolates are tested for acid production from mannitol, for growth response on mannitol salt agar plates (Difco Laboratories), and for susceptibility to a standard panel of antibiotics.[17–19] Ciprofloxacin susceptibility has been tested since May 1987 and resistance to ciprofloxacin was defined as a minimal inhibitory concentration ≥4.0 μg/mL. Isolates that differed by ≥3 of 13 findings in their antibiogram and biochemistry profiles were categorized as different.

The Phage Typing Unit MRSA laboratory records were reviewed for all isolates submitted between May 1, 1987 and June 30, 1988 that were resistant to ciprofloxacin. Isolates from 67 patients in 14 New York City hospitals and 14 patients in nine nursing homes (seven in New York City, two in bordering counties) were identified. The infection control practitioners of these 23 facilities were requested to complete for each patient a standardized data collection form based on the Centers for Disease Control National Nosocomial Infections Surveillance System Infection Worksheet. Data were collected concerning demographic factors, medical history, surgical procedures, cultures obtained, antibiotic treatment, hospital course, and outcome. Data were also collected concerning any patient at the facility who had a culture that revealed MRSA resistant to ciprofloxacin that was not submitted to the Phage Typing Unit.

Data on 43 patients were submitted by nine (64.3 percent) of the hospitals which are located in Manhattan (five) and Brooklyn (four) [the five nonparticipating hospitals are in Manhattan (two), Queens (two), and Brooklyn (one)]. Data on 12 patients were submitted by eight (88.9 percent) of the nursing homes which are located in the Bronx (four), Manhattan (one), Queens (one), Westchester (one), and Nassau (one); (the nonparticipating nursing home is in Brooklyn). Patients with positive cultures from normally sterile body sites or who were treated with antibiotics for positive cultures were considered infected; all others were considered colonized.

The data were coded and computerized using DBase III software. Statistical methods used included chi-square tests

for independence and Fishers exact test. Odds ratios (OR) and 95% confidence intervals (CI) were calculated.

Results

The Patients

The first positive culture for ciprofloxacin-resistant MRSA in New York City was obtained from a patient in late January 1988. Prior to that time, ciprofloxacin-resistant MRSA had not been reported in New York City. Of the 55 patients on whom we have reports, 30 were males, 25 were females, and the age range was 23 to 96 years, with a mean of 67.5 years and a median of 73 years. The mean age of the nursing home patients (71.8 years) was five years greater than that of the hospital patients. The principal diagnoses at admission were cerebrovascular accident (16.4 percent), pneumonia (12.7 percent), atherosclerotic heart disease (9.1 percent), sepsis (9.1 percent), and gangrene/cellulitis (7.3 percent), with other diagnoses accounting for two or fewer patients each. Two patients had the acquired immunodeficiency syndrome (AIDS). In addition, seven patients had insulin dependent diabetes mellitus and four had a reported history of intravenous drug use; none were on hemodialysis.

Almost half of the hospitalized patients were admitted from home, while three-fourths of the nursing home patients were transferred from a hospital (Table 1). The median time from admission to the first positive culture for MRSA was 25 days for 38 of the hospital patients and 340 days for the nursing home patients. Of the nine hospital patients who had a positive culture within one week of admission, five were admitted from home, including the two patients with a positive culture on the day of admission, three were admitted from a nursing home, and one was transferred from another hospital. The one nursing home patient who had a positive culture within one week of admission had been transferred from a hospital. At least 26 (47.3 percent) of the patients had at least one prior culture negative for ciprofloxacin-resistant MRSA and 14 patients had previous treatment with systemic antibiotics.

The culture source of each patient's initial MRSA isolate is listed in Table 2. All eight bacteremic patients and 20 of the 22 patients with positive pulmonary or sputum cultures were hospitalized. Of the 22 patients with a sputum or pulmonary source, 13 had definite radiologic evidence of pneumonia and three had possible radiologic evidence of pneumonia. Almost half of the patients had an identifiable risk factor for a nosocomial infection. Of the 21 deaths, MRSA was estimated by the clinical staff to have contributed to the deaths of at least five.

At least one antibiotic had been used for 52 of the 55 patients and 24 were treated with ciprofloxacin, 19 of whom began taking ciprofloxacin at least two days before the first MRSA positive culture was obtained. None of eight patients with a culture positive for MRSA within one week of admission received ciprofloxacin (data were unavailable for one patient). Twenty-two additional patients who did not receive ciprofloxacin were infected or colonized with ciprofloxacin-resistant MRSA. Ciprofloxacin use among the nursing home patients (75.0 percent) was greater than its use among the hospital patients (OR = 5.6, 95% CI = 1.1, 27.0).

TABLE 1—Places from Which Patients Were Admitted, by Patient's Facility at Time of Culture

Admitted From	Facility at Culture: Hospital, n	Facility at Culture: Nursing Home, n	Total, n
Home	21	1	22

Wound	14	Previous incision	4	1
Other	3	Invasive procedure	2	0
Total	55	Any noted above	26	21

The MRSA Isolates

The phage susceptibility of the ciprofloxacin-resistant MRSA are listed by facility in Table 3. The distribution of phage types differed between the hospitals and the nursing homes, with 57 percent of the isolates from the hospital patients that were typed susceptible to experimental phage 88 and 64 percent of the isolates from the nursing home patients that were typed susceptible to phages of International Group III. When facilities were grouped by geographic location, no singular or unique pattern was identified.

Ten facilities identified more than one patient with ciprofloxacin-resistant MRSA. The antibiograms, biochemistry tests, and phage typing of the isolates from nine of these facilities are available. Table 4 lists the number of different phage types and antibiogram/biochemistry patterns by facility. Three hospitals and one nursing home identified isolates with multiple phage groups and multiple antibiogram/biochemistry patterns. In one hospital (M-2) there was a close association between the phage groups and the antibiogram/biochemistry patterns, in two of the facilities (hospital K-1 and nursing home B-1) there was a variable association, and in one hospital (M-4) there was no association.

Discussion

In this investigation, we document the emergence of ciprofloxacin-resistant MRSA in New York City health care facilities, which was first noted in 1988.[19] The data are incomplete and represent a minimal account, however, because not all facilities report MRSA and submit all isolates to the NYCDOH and not all facilities that did submit isolates participated in this survey. In addition, this retrospective analysis was limited to MRSA isolates and not other *S. aureus* isolates. Finally, the patients may have been misclassified as being infected or colonized, because patients could have been treated with antibiotics inappropriately and because not all culture data were provided on each patient. Nevertheless, several important conclusions can be reached.

The ciprofloxacin-resistant strains appear to have emerged independently at a number of the health care facilities. This was also seen in the broader survey of reported quinolone-resistant *S. aureus* isolates in New York City.[19]

[a]Experimental phages excluding phage 88

The distribution of ciprofloxacin-resistant MRSA detected may represent either actual differences between hospitals and nursing homes, differences in community flora, or selective underreporting by facilities in other New York City boroughs. If the difference between the facilities is real, it is possible that MRSA isolates with this resistance pattern are transferred only between similar facilities locally, and we did note a few patients who may have been the vectors of transmission between facilities. Although nursing home patients have been prospectively implicated as a source of MRSA in Chicago hospitals,[8] half of the hospital patients we studied came from their homes, and colonized nursing home residents did not appear to be the major source of ciprofloxacin-resistant MRSA in the hospitals. Similarly, although the majority of the nursing home patients came from hospitals, many had a prior culture negative for ciprofloxacin-resistant MRSA and this admission pattern may be the usual one for nursing home residents.

*See footnote Table 3.

Ciprofloxacin-resistant MRSA, which contributed to almost one-fourth of the deaths and which resulted in an outbreak that eventually affected over 40 patients in one of the hospitals (Michael S. Simbercoff, MD: personal communication) appears as virulent as other *S. aureus* strains.[20] In this investigation, the majority of patients had MRSA resistant to ciprofloxacin without prior ciprofloxacin treatment. Therefore, ciprofloxacin may not be useful as a first line antibiotic, especially in facilities where ciprofloxacin-resistant MRSA is already prevalent.[21] Although data indicating that the prevention of resistance to ciprofloxacin by combination chemotherapy are few, ciprofloxacin may best be used in combination with other agents.[22–25]

We recommend that isolates of *S. aureus* be tested for susceptibility to ciprofloxacin in all health care facilities where ciprofloxacin is used. This increased testing provides clinicians with additional information necessary to prescribe appropriate treatment and allows additional surveillance opportunities to further define the spread of ciprofloxacin-resistant MRSA. In New York City, the Phage Typing Unit received 717 ciprofloxacin-resistant *S. aureus* isolates from 31 hospitals and 28 nursing homes from July 1 to December 31, 1988. 23 percent of the 3134 MRSA isolates submitted for phage typing (New York City Department of Health: unpublished data).

MRSA, in general, is becoming more problematic to health care facilities in New York. In a 1987 New York State Department of Health statewide survey, 40 (36 percent) of 111 acute care hospitals reported that they were adversely affected by MRSA. Furthermore, 23 outbreaks of nosocomial MRSA were reported in New York City health care facilities between July 1, 1987 and December 31, 1988 (New York State Department of Health: unpublished data). In response, the Department is promoting policies for health care facilities, based in part on those of the Los Angeles County Department of Health[26] and the Centers for Disease

Control[27,28] which emphasize the importance of traditional infection control measures, i.e., surveillance, handwashing, barrier precautions, epidemiologic assessment and appropriate cultures, individualized treatment, and intra- and inter-facility communication. Additional prevention and control measures have been described elsewhere[29] and have been discussed in a recent review.[30] Health care facilities may also find the surveillance of certain prescribed antibiotics and their control useful.[30–33] Finally, health care facilities need to work together to control the spread of MRSA and to provide the appropriate level of care for colonized or infected patients.

Access to Obstetric Care in Rural Areas: Effect on Birth Outcomes

Thomas S. Nesbitt, MD, MPH, Frederick A. Connell, MD, MPH,
L. Gary Hart, PhD, and Roger A. Rosenblatt, MD, MPH

Abstract: Hospital discharge data from 33 rural hospital service areas in Washington State were categorized by the extent to which patients left their local communities for obstetrical services. Women from communities with relatively few obstetrical providers in proportion to number of births were less likely to deliver in their local community hospital than women in rural communities with greater numbers of physicians practicing obstetrics in proportion to number of births. Women from these high-outflow communities had a greater proportion of complicated deliveries, higher rates of prematurity, and higher costs of neonatal care than women from communities where most patients delivered in the local hospital. (*Am J Public Health* 1990; 80:814–818.)

Introduction

A fundamental precept of modern obstetrics is that adequate prenatal care leads to improved perinatal outcomes for mothers and infants particularly for high risk populations.[1–3] For pregnant women to obtain timely and appropriate perinatal care, they must establish relationships with individual providers: obstetricians, family physicians, midwives, or public health nurses.

In the rural United States—accounting for 23 percent of the nation's population[5]—two-thirds of the obstetrical providers are family or general practitioners.[6] There has been a precipitous decline over the past several years in the number and proportion of family physicians offering obstetrical services in the United States. In 1988, only 29 percent of the members of the American Academy of Family Physicians were offering routine obstetrical care, down from an estimated 40 percent just two years previously.[7,8] Although approximately 43 percent of *rural* family physicians continued to offer obstetrics, this constitutes a 23 percent decline in their participation since 1980.[7,9] The Institute of Medicine reports that thousands of rural physicians stopped offering obstetrical care, leaving hundreds of rural counties without any local source of obstetrical services.[6] Although the cause of physicians eliminating obstetrical care from their practices is multifactorial, the cost of liability insurance and the fear of suits appear to play a major role in their decisions.[6,8–13]

Even in communities with adequate obstetrical care, a certain proportion of women either choose to leave these communities for obstetrical care, or are referred to different physicians or facilities because of specific complications of pregnancy. However, in towns with little or no obstetrical capacity, most women must travel to secure basic prenatal care as well as delivery. As a consequence it becomes less likely that those women will obtain adequate prenatal care.[14] Delays in care of early labor complications may also result.

This study investigates the extent to which local availability of obstetrics is related to perinatal outcomes. We seek to answer the following questions:

- What are the characteristics of rural communities in which the majority of women deliver at a facility other than their local hospital (outflow)?
- Using outflow as a proxy for access to care, is there any difference in the outcome or cost of care for women living in communities with diminished obstetrical access as compared to women who have ready access to local obstetrical care?

Methods

Population Studied

The study was based on all deliveries of women whose primary residence was in a rural area of Washington State and who gave birth during calendar year 1986. The following definitions were used:

- *Rural hospitals* were defined as all non-federal, short-stay, acute care, inpatient facilities of fewer than 50 beds and located more than 15 miles from a city of 30,000 population or greater. Thirty-three of Washington's 90 hospitals met these criteria.
- A *rural area* was defined as the medical service catchment area served by these hospitals.
- A *catchment area* was the aggregate of all zip code areas whose center was closer to a specific rural hospital by public road than to any other hospital facility.
- Distances were based on figures supplied by the Washington State Department of Transportation.

Stratification of Rural Areas by Location of Delivery

A file of all hospital discharges from non-federal, short-stay hospitals in the State of Washington includes data on the place of residence of the patient, hospital of discharge, the DRG (diagnosis related group), and hospital charges. Maternal residence was used to identify all patients living within the 33 rural medical service catchment areas. By comparing the place of residence with the location of the hospital of delivery, we could determine what proportion of all obstetrical deliveries occurred in facilities outside a woman's local hospital catchment area.

The 33 rural areas were stratified into three groups on the basis of these determinations. Areas in which more than two-thirds of deliveries occurred in the local hospital were designated as "low-outflow" communities. "High-outflow" communities were those in which fewer than one-third of deliveries to local women occurred in the local hospital.

This paper, submitted to the Journal July 25, 1989, was revised and accepted for publication November 8, 1989.

© 1990 American Journal of Public Health 0090-0036/90$1.50

"Medium-outflow" communities were those between these two extremes.

Availability of Obstetrical Services

The availability of obstetrical services in each of the 33 communities was determined through telephone surveys of hospital administrators and directors of nursing. The response rate was 100 percent. Information was obtained as to the number and specialty of all physicians providing obstetrical services in each hospital during the study period (1986), as well as in 1985 and early in 1988. A physician was considered as providing obstetrical services if, in the opinion of the administrator and directors of nursing, the physician was routinely doing deliveries in the hospital; this excluded physicians who delivered only on an emergency basis.

Determining Pregnancy Outcome and Costs

DRGs were used as proxies for obstetrical outcome (Appendix). Maternal complications were defined as all discharges with DRGs 370 or 372. These DRGs are used to designate deliveries—both cesarean section and vaginal—associated with major intrapartum complications, as well as other conditions such as pregnancy-induced hypertension, diabetes, and anemia. The balance of the deliveries were assumed to be uncomplicated for the purposes of this study and included DRG 371 (uncomplicated C-section), 373 (normal vaginal delivery), and 374 and 375 (vaginal delivery with an operating room procedure, such as sterilization). Premature births were defined as babies discharged with DRG codes 386, 387, or 388 all of which referred to premature delivery. DRGs 389, 390, and 391 were defined as full term births.

Hospital charges for neonatal care, as well as source of payment, were also evaluated from the hospital discharge abstracts.

Statistical Analysis

Differences in outcomes between outflow groups were evaluated using chi-square for trend for each outcome measure. Hospital charges for newborns were evaluated by comparing the means of high and low outflow communities, and the confidence interval of the difference between them. In addition, for the same groups, the proportion of newborns with charges greater than $5,000 were compared using the associated 95 percent confidence interval of the difference between those proportions.

Results

Characteristics of Study Communities

Approximately 350,000 people, 8 percent of the population of Washington State, live in the 33 rural medical service areas defined by this study. The 33 hospitals serving these areas represent 37 percent of the 90 acute, short-term, general hospitals in Washington State, but account for only 8 percent of the total licensed acute care beds. These service areas are dispersed throughout the state; 23 of Washington's 39 counties encompass one or more of the study areas. The 5,554 births which occurred to residents of these areas in 1986 represent 8.1 percent of all births to residents of the state during that year. There were 108 physicians practicing obstetrics in the 33 communities during 1986, 93 percent of whom were family or general practitioners; there were eight obstetricians practicing in two low-outflow communities and two medium-outflow communities.

As can be seen from Table 1, both the rural communities and the hospitals that serve them are quite small, with the average service area encompassing 10,592 people and the average hospital having 32 beds. High-outflow communities—those in which more than two-third of all births to local residents did not occur in the local hospital—were smaller than communities where larger proportions of pregnant women delivered in their local community hospital. These high-outflow communities were also somewhat closer to other more sophisticated perinatal facilities, although even for this group the average distance to a Level II facility was 41 miles. Conventional measures of socioeconomic status, such as unemployment rate and the proportion of obstetrical patients enrolled in Medicaid, did not meaningfully differ among the three groups of communities.

The most striking difference between the communities in the outflow groups was the local availability of obstetrical care. By the end of the study period in 1986, only eight of the 13 high-outflow community hospitals still offered routine obstetrical services, with four of the closures occurring since mid-1984. Additionally, three of the eight hospitals which offered obstetrical services in 1986 suspended these services

TABLE 1—Characteristics of Study Communities Stratified by Differential Obstetrical Outflow, Washington State, 1986

Characteristics	Low Outflow (<33%) N = 8	Medium Outflow (33–67%) N = 12	High Outflow (>67%) N = 13	All Communities N = 33
Total number of hospital births to residents of service areas	1,155	2,781	1,618	5,554
Percent of births occurring outside community	19.9	48.8	80	52
Mean miles to Level II nursery	79	63	41	58
Mean beds in local hospital	37	33	27	32
Mean population of hospital service area	11,029	12,318	8,731	10,592
Mean percent of obstetrical patients enrolled in Medicaid	31.3	26	27.4	28.8
Mean percent county unemployment rate (1985)	12.6	11.8	11.1	11.7
Percent of births to women under 18 or over 35 (1986)	9.4	11.0	8.8	9.7
Infant Mortality Rates/1000 births (County rates 1980–83)	11.6	11.8	10.5	11.2

in either 1987 or 1988. The reason given in essentially all of these cases was the decision of local physicians to discontinue offering obstetrics. All of the low and medium-outflow communities continued to offer obstetrics. Figure 1 shows that high-outflow communities had relatively fewer obstetrically active physicians in the year before the study, and that this disparity has become more pronounced during the study year and in the succeeding year. By contrast, there was no significant attrition in obstetric availability in the comparison communities.

Obstetrical Outcomes

Obstetrical outcomes differed systematically across the three groups of communities. As Figure 2 demonstrates, there is a strong association between the proportion of deliveries that occur outside of the community and the rate of complications associated with childbirth. Women living in high-outflow communities were 34 percent more likely to experience birth-associated complications or comorbidity than women from medium-outflow communities, and 67 percent more likely than women from low-outflow communities.

Children of women from high-outflow communities have higher rates of prematurity, a trend significant at the .001 level. Neonatal length of stay—a measure presumably correlated with neonatal outcome—also shows a significant trend across community type.

Access to Care and Perinatal Costs

Table 2 illustrates the difference in hospital charges for newborns used as a proxy for cost for neonatal care across the three community groups. Newborn patients from high-outflow communities have dramatically higher average charges than their counterparts in better served communities.

Although the differences are impressive without regard to insurance type, it appears these differences are mainly the result of patients enrolled in the Medicaid program. It should be noted, however, that infants of lower income women with adverse birth outcomes generating high hospital charges are more likely to be encouraged, and even assisted in enrolling in Medicaid.

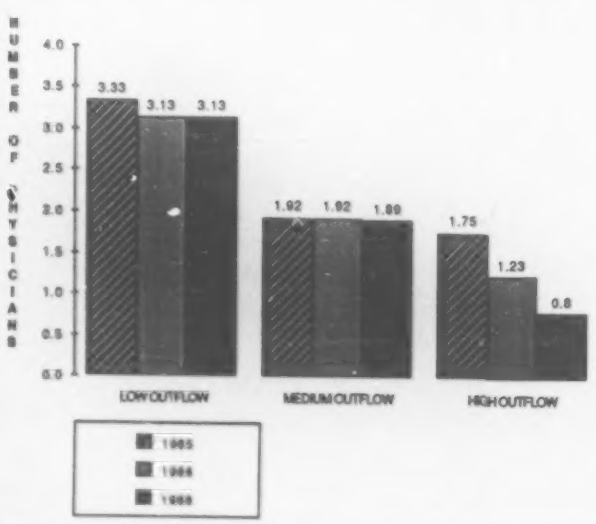

FIGURE 1—Physicians Practicing Obstetrics per 100 Births to Local Women by Community Outflow by Selected Year

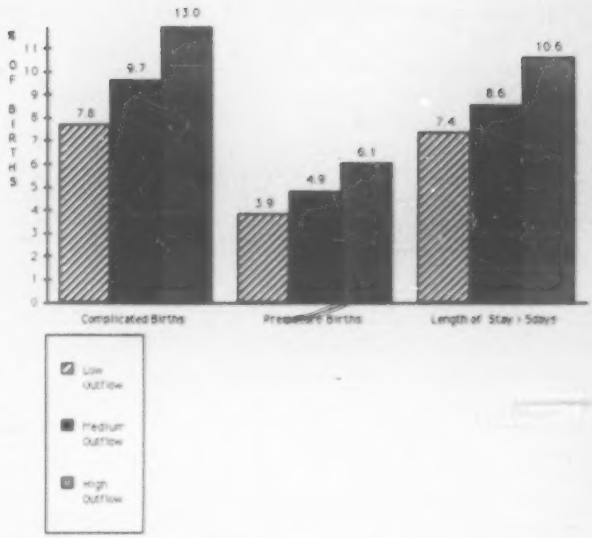

FIGURE 2—Percent of Adverse Birth Outcomes to Rural Washington State Residents by Community Outflow

TABLE 2—Newborn Hospital Charges to Rural Washington Residents Stratified by Community Outflow for Obstetrical Care and Payor Type

	Mean Charges		
	High Outflow N = 1587	Low Outflow N = 1210	Difference (95% CI)
All payors	$2,103	$1,046	$1057 (−$125, $2,239)
Medicaid	$4,627	$1,014	$3613 (−$422, $7,648)
Non-Medicaid	$1,128	$1,061	$67 (−$368, $502)
	Proportion of Newborns with Charges > $5,000		
	High Outflow N = 1587	Low Outflow N = 1210	Difference (95% CI)
All payors	3.6	1.7	1.9 (0.66, 3.14)
Medicaid	6.3	2.1	4.2 (0.54, 7.9)
Non-Medicaid	2.7	1.4	1.3 (−.03, 2.57)

Although a few outliers can generate enormous charges, dramatically increasing the mean, and they undoubtedly had an effect here, newborns with higher charges clearly occurred more frequently in high outflow community populations. As shown in Table 2, there are three times as many babies on Medicaid with charges exceeding $5,000 in the high-outflow communities compared to the low-outflow communities—a measure less affected than average charges by the influence of extreme outliers.

Discussion

The declining proportion of practitioners offering obstetrical services has had a disproportionate impact on rural areas. First, rural areas have fewer physicians per capita than urban regions and thus are more susceptible to changes in the spectrum of clinical services offered by those physicians who

do practice in rural America. Second, a larger proportion of deliveries in rural areas have been provided by general and family physicians, a group that has experienced a high rate of attrition from obstetrics.[6,7–13,15]

Out data demonstrate that women living in rural Washington state communities with little or no obstetrical care available locally tend to deliver in hospitals outside the community. These women are more likely to have complicated labor and premature deliveries, and their infants are more likely to have longer and more expensive hospital stays than the children of their rural counterparts who deliver in local facilities communities with greater access to care.

The design of this study does not permit us to conclude that there is a causal relation between impaired access to rural obstetrical care and adverse perinatal outcome, although this appears to be a tenable hypothesis. There are several possible mechanisms which could account for a causal relation between access to care and outcome, however. First, women living in communities without obstetrical services must travel to obtain routine prenatal care, a barrier associated with poorer prenatal compliance.[14] Women on marginal incomes or women without adequate transportation would be likely to delay or forego prenatal care, and might have more difficulty getting to all their prenatal visits. Even if these patients are able to arrange for transportation to other communities, they may encounter difficulties in obtaining obstetrical care in a state like Washington where most physicians limit the number of pregnant Medicaid patients for whom they will provide care.[10]

Second, obtaining obstetrical care and delivering outside one's local community may in itself constitute a risk factor for adverse outcome, even if obstetrical care has been arranged. Patients from remote, rural communities may have difficulty adhering to prenatal protocols or treatment regimens prescribed by physicians in distant communities. There may be significant delays in presentation to the hospital after the onset of labor. And the increased stress—physiological and psychological—associated with travel and parturition in unfamiliar settings may interfere with the normal process of labor.

Nevertheless, there are alternative explanations for the patterns observed here, the first being the possibility that inappropriate care was delivered by local physicians in high outflow communities. This is an unlikely cause for the results in this study for several reasons. First, there was little care available in these communities; five were without any routine obstetrical services. Second, for the 20 percent of the women from high-outflow communities who did deliver in a local hospital, outcomes were actually superior to local deliveries in medium and low-outflow facilities. Finally, of the non-local complicated births which occurred to women from high outflow communities, less than 5 percent came to those non-local hospitals as the result of a transfer.

A second explanation is that because the data are derived from hospital discharge abstracts, we lack precise information about the prenatal, intrapartum, and neonatal course of the patients in the study. DRGs and costs are used as proxies for outcome, and it is possible that there is a systematic bias in which larger urban hospitals are more likely to intervene medically during the intrapartum period, assign DRG codes denoting increased medical intensity, and keep neonates longer in their nurseries than smaller rural hospitals. Even if such a bias is the cause of the apparent differences in biological outcomes, the increased charges and lengths of stay associated with deliveries outside rural communities are real.

A third alternative explanation for the observed disparities is that women from communities with high-outflow are not comparable to the women living in medium- and low-outflow communities. Perhaps the 13 communities in this group have populations of women with higher risks for adverse perinatal outcomes. However, we found no indications that these high-outflow communities differ systematically from those with lower outflow for obstetrical care. Although the high-outflow communities are slightly smaller than the average rural Washington town or medical service area, the situation regarding previous county infant mortality rates (80–83), county unemployment, and the percent of obstetrical patients on Medicaid from these communities is similar to that of communities with less outflow and better outcomes.

A fourth explanation for these results may be that physicians in communities with increased rates of adverse outcomes transfer those high-risk patients to outside facilities prior to labor, thereby becoming a high-outflow community. However, if one notes that high-outflow communities were those in which more than two-thirds of the patients delivered non-locally, and that these communities had only 13 percent complicated births, it is clear that the transfer of an increased number of complicated patients would not change an otherwise low-outflow community into a high-outflow community.

Despite the limitations of this study, the data suggest that recent declines in the availability of obstetrical care in rural areas are associated with poorer perinatal outcomes. From the experience in Washington State it appears that the pivotal event is the decision by rural family physicians to discontinue providing obstetrical services. In many cases this leads to a substantial curtailment or total discontinuation of obstetrical services in the local hospital, causing women who may have previously delivered in their local hospital to travel to other communities for their obstetric care.

Although in this study loss of local services and associated higher rates of adverse outcomes were observed only in a handful of relatively small communities, this may be the leading edge of a more pervasive phenomenon. Although the problem is more graphic and easily demonstrated in rural populations, impaired obstetrical access may have the same social and biological consequences in urban settings.[16]

This study suggests that programs that maintain local availability of obstetrical care may improve perinatal outcomes in a cost effective fashion, since infants from high-outflow rural communities generated hospital charges twice as high as infants from low- and medium-outflow communities. The excess charges were more than $1.5 million during 1986 alone, most of it paid for by public subsidies through the Medicaid program. This does not include additional costs in the post-hospital period which have been shown to be higher for Medicaid infants whose mothers received inadequate prenatal care.[17]

In conclusion, this study demonstrates an association between diminished rural access to obstetrical care and perinatal outcomes for women who travel outside their local communities for that care. If a causal relationship exists, society would benefit both medically and economically from providing a solution to the problems which stem from a diminishing number of obstetrical providers.

'Late Breaker' Session on Injury Control Invites Abstracts

The Injury Control and Emergency Health Services special primary interest group of the American Public Health Association has announced it will again feature a "late breaker" session during the APHA upcoming 118th annual meeting in New York City. The session will be held on Tuesday, October 2, 8:30 am–10:00 am, and will feature work completed within the last few months--after the deadline for consideration in the regular symposia of the APHA annual meeting.

Abstracts of 250 words or less will be accepted by the Injury Control SPIG until August 15, 1990. Please send the abstract, title of the paper, authors' name, address and telephone number to: Richard Waxweiler, Division of Injury Control, Centers for Disease Control, Mail Stop F-36, Atlanta, GA 30333. Tel: 404/488-4695.

The Relation of Obstetrical Volume and Nursery Level to Perinatal Mortality

JENNIFER A. MAYFIELD, MD, MPH, ROGER A. ROSENBLATT, MD, MPH, LAURA-MAE BALDWIN, MD, MPH, JOSEPH CHU, MD, MPH, AND JAMES P. LOGERFO, MD, MPH

Abstract: We investigated the relation of hospital delivery volume and nursery technology level to perinatal outcome in 226,164 White singleton births in Washington State, 1980–83. Level III facilities (neonatal intensive care unit) were defined by the state licensing commission. We defined the Level II (intermediate) and Level I (normal newborn) facilities using published criteria. Infants under 2000 gm born in Level III facilities had half the risk of perinatal death compared to those born in a Level I or II facility. No significant improvement was noted among level or volume groupings for normal birthweight infants. A loglinear regression model of hospital perinatal death rates showed that when birthweight and maternal risk were controlled, obstetrical volume added minimal explanatory power to level of nursery care. (*Am J Public Health* 1990; 80:819–823.)

Introduction

Many experts believe that the decreasing rates of neonatal and perinatal death observed in the United States over the past several decades are due to more effective technological interventions coupled to regionalization, a process which optimizes access to that technology.[1,2] Regionalization is based on a tiered structure of facilities linked by referral patterns whereby high-risk mothers and newborns are triaged to the central facilities with increased technology and staff. Most investigators have noted a twofold improvement in outcome for infants under 2500 gm when born in a high technology facility (Level III) compared to birth in a low technology facility (Level I).[3–7]

A close correlate of high technology is volume, since a high volume of patients is required to justify the expense of purchase, maintenance, and staffing of high technology. This high volume is also thought to lead to improved skill in the use of the technology. Work by Luft and others has shown a positive relation between the quality of care and hospital volume of some surgical procedures and medical diagnoses.[8–10] Increased obstetrical volume also appears to impart some benefit in obstetrical outcome, with authors noting the death rates for infants delivered in facilities with over 2,000 deliveries/year to be half of the rate of those born in facilities delivering less than 500 per year, particularly for the low birthweight infants.[3,11,12]

The relation among volume, technology level, and outcomes is unclear. Most of the studies of obstetrical volume are confounded by the presence of high technology. For example, when Williams evaluated the relation of hospital characteristics to mortality, obstetrical volume became insignificant when variables that normally accompany higher technology, such as higher number of specialists and C-sections, were added to the regression.[12]

This study was undertaken to establish more clearly the relation of hospital obstetrical volume and neonatal nursery technology to outcome by using the perinatal mortality rate as the outcome measure of quality. Also, we desired to explore the relation between obstetrical volume and the nursery level of care.

Methods

Perinatal Data

Washington State birth-death linked records and fetal death records were obtained for 1980–83. The analysis was restricted to White singleton births because of the very small number of other racial births and their marked association with high volume hospitals. All White singleton births over 1000 gm which occurred in hospitals that routinely offer obstetrical care in Washington State were included. The hospital of birth (not of death) was identified from the record, and births were grouped by hospital. Perinatal death was defined according to the World Health Organization, i.e., all fetal deaths over 1000 gm and all live births over 1000 gm which died within one week of birth (early neonatal deaths).[13] Births under 1000 gm and those without a recorded birthweight were excluded from the study. The birthweight was stratified by 250 gram intervals for analysis, then grouped by 500 grams for presentation in the tables.

The fetal file required special handling because no birthweight was recorded for 450 cases (23 percent) of the fetal death file. We obtained 91 of the missing birthweights from a chart review being conducted by the Washington State Department of Social and Health Services, Division of Health, Epidemiology Section.[14] The last menstrual period was recorded on 223 of the records sans a birthweight, enabling us to calculate a gestational age. We elected to impute birthweights based upon this calculated gestational age, using the mean birthweight per gestational week from the 1981 live birth file as a standard. There were 171 fetal deaths without a birthweight or gestational age recorded. (Further details can be obtained from the first author.)

We controlled for maternal risk factors recorded in the certificate which might influence the choice of hospital.[15,16] A high-risk status was declared if any of the following were noted on the certificate: all forms of diabetes, hypertension, pyelonephritis, pregnancy-induced hypertension, acute urinary tract infection, surgery, tumor, epilepsy, prior fetal death, pre-eclampsia, eclampsia, Rh-sensitization, abruptio placenta, placenta previa, or "other medical problems."

Hospital Characteristics

The obstetrical volume per year was calculated as the average of all deliveries performed in that facility over the four study years, 1980–83.

All six Level III facilities currently recognized and licensed by the state as Level III were assigned Level III status. We assigned Level II status using published guidelines

(see Appendix).[17] The remainder of the facilities were considered Level I facilities.

Data Analysis

Simple descriptive analyses were used to examine the relation between variables and to calculate the relative risks of death. Confidence intervals were developed using the Mantel-Haenszel Chi-square statistic test-based method.[18] A log-linear model was created, using the Generalized Linear Model (GLIM) statistical package. The dependent variable was the likelihood of death in each hospital and the independent variables were obstetrical volume, nursery level, maternal risk status, and birthweight. The model additions were tested for significance using the deviance based method, where the model is compared to the nested model by comparing the difference in scaled deviance and difference in degrees of freedom in a Chi-square contingency table.[19]

Results

Data Description

Washington State Department of Vital Statistics recorded 280,801 live births, 1,377 early neonatal deaths, and 2,046 fetal deaths for the study years 1980–83. We excluded live births and fetal deaths that were delivered in non-obstetrical hospital settings (6%, 6% and 6%), multiple gestations (i.e., twins) (2%, 11% and 9%), and of non-White race (12%, 12% and 17%). White singletons born in an obstetrical hospital that had a birthweight under 1000 gm (live births (.3%), neonatal deaths (41%) and fetal deaths (32%)) or were missing a recorded birthweight (live birth (.4%), neonatal deaths (4%), and fetal deaths (4%)) were excluded from analysis. There were 225,287 live births, 495 early neonatal deaths and 877 fetal deaths of White singletons which occurred in the 90 Washington state hospitals which routinely offer obstetrical care. This made a total of 226,164 births and 1,372 perinatal deaths.

Table 1 shows the distribution of the 90 hospitals between facility level and obstetrical volume groups. A high degree of correlation is noted between level and obstetrical volume groups. The distribution of births and perinatal deaths between level and obstetrical volume along with the crude perinatal mortality rate is shown in Table 2. Level III facilities had the highest crude death rate.

Stratified Analyses

The birthweight distribution was highly related to the hospital's level of technology. The distribution of births among the three levels is shown in Table 3, showing a significant shift in birthweight distributions across level. The lower the birthweight, the more likely the infant to be born in a Level III setting. While Level III hospitals deliver only 22 percent of all births, almost 40 percent of low birthweight infants (1500–2500 gm) and 67 percent of very low birthweight infants (1000–1500 gm) were born in Level III settings. The distribution of births among the five volume groups is similar to the distribution among levels, with low birthweight babies concentrated in larger volume facilities.

The birthweight-specific perinatal mortality rate by level of facility is shown in Table 4. The infant under 2000 gm was twice as likely to die if born in a Level I or II facility compared to a Level III. For the infant over 2000 gm, level of care had little influence on survival rates. The birthweight-specific perinatal mortality rate is compared across obstetrical volume groups and is similar to that across level of facility. The infant under 2000 gm had twice the mortality rate in facilities with less than 2,000 deliveries per year when compared to those born in facilities with more than 2,000 deliveries per year, while little difference existed between obstetrical volume groups for infants over 2000 gm.

TABLE 1—Distribution of Hospitals Among Nursery Levels and Obstetrical Volume Groups

	Volume Groups (births/year)					
Nursery Type	<200	201–500	501–1000	1001–2000	>2000	Total
Level I (normal)	31	22	13	7	0	73
Level II (intermediate)	0	0	1	5	5	11
Level III (intensive care)	0	0	0	0	6	6
Total	31	12	14	12	11	90

TABLE 2—Crude Perinatal Mortality for the Level and Volume Groups

	Deaths	Births	Crude PNMR (deaths/1000 births)
Level I (normal)			
<200 births/yr	65	8,267	7.8
200–500 births/yr	201	23,275	8.6
500–1000 births/yr	269	30,928	9.3
1000–2000 births/yr	301	40,518	7.4
Level II (intermediate)			
500–1000 births/yr	20	2,337	8.5
1000–2000 births/yr	303	27,827	11.2
>2000 births/yr	314	43,261	7.2
Level III (intensive care)			
>2000 births/yr	793	51,161	15.5

TABLE 3—Distribution of Births Among Level by Birthweight

	Level			Total	
Birthweight	I (%)	II (%)	III (%)	(%)	(n)
1001–1500 gm	17	16	67	100	924
1501–2000 gm	25	20	55	100	1,829
2001–2500 gm	39	29	32	100	6,214
2501–3000 gm	45	31	24	100	27,136
3001–3500 gm	46	32	22	100	79,229
3501–4000 gm	46	33	21	100	76,900
>4001 gm	46	34	20	100	33,932
Total	45	33	22	100	226,164

TABLE 4—Birthweight-Specific Perinatal Mortality Rates by Level (Deaths/1000 births)

	Level			
Birthweight	I	II	III	Total
1001–1500 gm	459	358	175	253
1501–2000 gm	170	150	68	110
2001–2500 gm	31	38	39	36
2501–3000 gm	7.8	7.6	11.4	8.6
3001–3500 gm	3.5	2.8	3.0	3.2
3501–4000 gm	1.8	1.5	2.3	1.8
>4001 gm	2.2	2.8	3.7	2.7

Loglinear Regression

The loglinear regression models are shown in Table 5. The nested model used for comparison to determine the significance of the new variable is noted in the second column. As expected, the main effect of birthweight (Model B) was by far the most important variable, with a smaller contribution made by the addition of risk status (Model D), nursery level (Model E) but not the addition of obstetrical volume (Model F). The two major interactions noted in the stratified analyses between "birthweight—risk" (Model H) and "birthweight—level" (Model J) made significant improvements in the model. The addition of volume (Model K) made a significant addition to the model, indicating that volume had an effect above and beyond nursery level.

The model using the interaction between level and volume (Model L) was discarded since the large number of empty volume-level combinations left only one interaction term in the model (see Table 1). The addition of interaction between "volume-risk" (Model M) was also significant, but made the model very complex.

Unfortunately, there is no method currently available to calculate confidence intervals for the various models, since the models include interaction terms. Because the data is so large, most variable additions were statistically significant. However, when parameter estimates were converted into perinatal mortality rates and compared for Model K and Model M, the clinical significance was minimal. Based on this finding, Model K was chosen as the final model.

To provide some clinical perspective of this complex model created by the loglinear analysis, we calculated the number of deaths that would have occurred if all infants had been born in one type of a facility. For infants weighing 1000–2500 gm, the Level III facilities with over 2,000 births/year appeared most advantageous, and for infants over 2500 gm the Level I facilities with 1,000–2,000 births/year appeared most advantageous. Table 6 shows the number of deaths that would have been expected if all births had occurred in either Level I facilities with 1001–2000 births/year or in Level III facilities with >2000 births/yr.

TABLE 6—Observed Deaths and Deaths Predicted from the Model If All Births Occurred in One Type of Facility

Birthweight	Observed	Level I Volume 1000–2000	Level III Volume >2000
1000–1499 gm	234	425	213
1500–1999 gm	201	316	130
2000–2499 gm	221	204	264
2500–2999 gm	234	232	306
3000–3499 gm	251	301	281
3500–3999 gm	139	143	179
4000–4500 gm	47	35	81
>4500 gm	45	45	62
Total	1372	1701	1517

Discussion

The potential limitations of this study include the quality of the vital statistics data. First, missing data, inaccuracies, and underreporting could bias the results, especially if they occurred preferentially in selected level or volume group facilities. However, the failure to record birthweight was evenly distributed among all levels and volume groups of hospitals, minimizing this concern. Other studies comparing medical records to Washington State Vital Statistics records have noted no correlation between type or size of facility and recording omissions.[14,*] Second, the elimination of cases without birthweight creates an underestimation of the true birthweight-specific perinatal death rates, while the imputation of fetal cases using standards from live births would overestimate these rates. Third, certain variables of interest that may have affected the risk classification, such as smoking status of the mother and educational attainment, were not available on these records.

Our study's main purpose was to explore the relation between obstetrical volume and nursery level of care. While obstetrical volume and nursery level are highly correlated, the loglinear analyses indicate that nursery level has a stronger influence on the perinatal mortality rate. Technology, rather than the volume effect, appears most beneficial in lowering perinatal mortality rates.

M. " + Volume * Risk	K	55	4	<.001

*Indicates the inclusion of the main effects of both variables plus the interaction term (Z * Y = Z + Y + (Z × Y).

The benefits from technology (and to a lesser extent, volume) were not enjoyed by all groups of infants. The greatest benefits were achieved by low birthweight infants (<2500 gm) with a two-fold improvement in perinatal mortality rates noted when born in Level III nurseries compared to Level I or II. This finding is similar to other evaluations of regionalized nursery systems over the past decade.[3–7] The normal birthweight infant, on the other hand, realized no net benefit from the technology-intense Level III facility. In fact, they had marginally better survival when born in the low technology setting of Level I hospitals than if born in a Level III facility, but this difference was not statistically significant. This finding is very similar to an analyses of the term, normal birthweight infant in an urban setting (New York City),[20] but different from Rosenblatt's finding in New Zealand[21] of statistically higher mortality for normal birthweight infants in Level III, high volume facilities. The lack of benefit for the normal birthweight infant in a high volume, technology intense setting could possibly be due to the failure of Level III facilities to recognize and record high-risk conditions. Because this potential ascertainment bias among nursery levels seems counter-intuitive, other explanations for the lack of benefit, and even possible harm, should be explored.

Perhaps the most interesting finding of this study was that Level II facilities did no better with infants weighing under 2000 grams than did Level I facilities. Level III facilities are approved by state authorities according to set criteria in Washington State, but no such external independent review occurs for Level II facilities. The published criteria differentiating a Level II is quite vague, specifying only that a "selected number of other services" would be offered above and beyond a normal nursery. Our Level II classification system included facilities that self-designate themselves "Level II+" and excluded hospitals offering fewer types of Level II services. Our conservative classification system should have exaggerated any possible difference between Level I and II. Prior evaluations of the influence of level have noted no improvement of Level II over Level I.[6,20,21] No evaluation to date has justified the division of nurseries into a three-level system.

The improvement in perinatal mortality rates in Level III compared to Level I facilities has been credited to the presence of neonatal intensive care units, but the specific features of the unit that ensure this improvement are unknown. Other factors which may influence survival include resuscitation capabilities (due to a practice effect), lower rates of "untreatable" conditions such as malformations, or a selection bias where less severe conditions present with sufficient time for transfer to a Level III, while more severe conditions present acutely to the Level I facility, prohibiting transfer or effective treatment.[22,23] Small area population based studies would assist in clarifying the influence of these factors.

The benefits and risks of regionalization should be evaluated from a system-wide perspective, taking into account all segments of the population. Our model simulation with all births occurring in Level I facilities predicted a marked increase in perinatal mortality, experienced especially by the low birthweight infant. This is consistent with the observations that perinatal mortality rates have improved as low birthweight infants have been centralized into Level III facilities. The model also predicts a higher number of deaths if all infants were centralized to a Level III facility, mainly from a large number of normal birthweight infants dying at a slightly higher rate. We suggest that the current system of intrauterine transfer is closer to an optimum composition, with most of the low birthweight infants being born in Level III facilities, and the majority of low-risk, term infants being born in Level I facilities. Further efforts to centralize the system, i.e., closing smaller hospitals, will be of no benefit to the normal, low-risk infant, and may even pose a risk to the normal birthweight infant.

The relation of volume to perinatal outcome is of more than academic interest to states with large rural populations such as Washington State. In 1984, over one-third of Washington State hospitals had less than 500 deliveries per year, the cutoff recommended by federal health planners in 1977 to ensure hospital quality.[24] These small hospitals now find themselves affected by the public's belief that big and better equipped hospitals offer better quality care and are bypassed by low-risk, term women who seek delivery in a Level III facility. This drain of obstetrical cases, compounded by other financial pressures and the loss of obstetrical providers, has forced many rural hospitals to eliminate their obstetrical services, resulting in access problems and even adverse outcomes for rural women.[25] Health planners and patients should be reassured with the knowledge from this and other evaluations[26] that the low volume Level I facility is an appropriate and safe location for birth for the term, low-risk woman.

In summary, the effect of hospital technology upon perinatal mortality appears to be greater than the effect of volume, but this benefit is enjoyed mainly by the low birthweight, high-risk infant. The evaluation of practices and policies which encourage transfer of obstetrical patients between facilities must consider the outcomes for all segments of the population to guide wise policy decisions and efficient resource allocation.

APPENDIX

Criteria for Level I and Level II Facilities

Criteria to differentiate Level II from Level I facilities were based upon guidelines published by the American College of Obstetrics and Gynecology and the American Academy of Pediatrics.[17] Our Level II criteria included:

- the presence of obstetric and pediatric medical staff,
- 24 hour in-house capability of resuscitating a newborn,
- maintenance of peripheral or umbilical lines, and
- short-term respiratory support.

A hospital had to meet all of the above criteria to be classified as a Level II facility. Information on nursery services and practices during 1980–83 was obtained by telephone interview with the hospital staff. Eleven hospitals met our criteria for Level II designation, and the remainder were labeled as Level I. The designation was reviewed and approved by the neonatologist who chairs the Washington State regionalization program.

Call for Abstracts

APHA 'Late-Breaker' Epidemiology Exchange Session

The Epidemiology Section will sponsor a "Late-Breaker" Epidemiology Exchange on Wednesday, Oct. 3, 1990, 2:00–5:00 pm, at APHA's 118th Annual Meeting to be held in New York City, Sept. 30–Oct. 4. The Exchange will provide a forum for presentation of investigations, studies, methods, etc., which have been conceived, conducted, and/or concluded so recently that abstracts could not meet the deadline for submission to other Epidemiology Sessions. Papers submitted should report on work conducted during the last 6–12 months.

Abstracts should be limited to 200 words; no special form is required. Abstracts should be submitted to Robert A. Gunn, MD, Division of Field Services, Epidemiology Program Office, Building 11 South, Mailstop F-15, Centers for Disease Control, Atlanta, GA 30333—Telephone: 404/639-0336; FAX 404/639-0277, and must be received by *August 13, 1990*. Receipt of abstract will be acknowledged by postcard and acceptance will be decided by August 17, 1990.

Infectious Disease Control in a Long-term Refugee Camp: The Role of Epidemiologic Surveillance and Investigation

CHRISTOPHER J. ELIAS, MD, BRUCE H. ALEXANDER, MS, AND TAN SOKLY

Abstract: This report demonstrates the role of epidemiologic surveillance and investigation in the control of infectious diseases in a long-term refugee camp. The applications of simple epidemiologic methods in a refugee camp on the Thai-Cambodian border are described for a one-year period. The development of a Health Information Office facilitated the collection of demographic and vital statistics data, administration of a disease surveillance system, regular monitoring of hospital and outpatient discharge diagnoses, and investigation of disease outbreaks. This office also organized community health education campaigns and disease control efforts. Examples of specific disease investigations are provided to demonstrate the utility of epidemiologic surveillance in the control of infectious disease. We conclude that simple epidemiologic methods play an important role in health planning in long-term refugee camps. (*Am J Public Health* 1990: 80:824–828.)

Introduction

There are currently more than 12 million refugees throughout the world.[1] Disease and famine often accompany the movements of refugees, as health and nutritional systems are disrupted by strife. Refugee camps are generally perceived as temporary structures requiring immediate, short-term assistance. Unfortunately, persistent war in the Middle-East, Afghanistan, Sub-Saharan Africa, and Southeast Asia has created refugee camps that require long-term assistance. These camps have become permanent settlements and are now home for the majority of the world's refugees. The health care problems of long-term camps differ from those of short-term camps; the primary tasks are health maintenance, nutritional support, community development, and training of refugee health workers.[2] These tasks are often more difficult than the highly publicized crisis management necessary during the emergency phase of refugee relief operations. The permanence of these camps, combined with the difficulty in obtaining ongoing support, demands innovative planning to effectively allocate scarce health resources.

The importance of epidemiologic assessment for public health planning and resource allocation has been emphasized in emergency assistance situations.[3,4] The successful use of simple epidemiologic methods has been demonstrated in the emergency phase of the Cambodian and Ethiopian refugee crises.[5,6] Epidemiologic assessment is equally important for dealing with the health concerns of long-term camps.[7] Effective disease surveillance and outbreak investigation can help direct public health interventions. Analysis of mortality trends and nutritional status can be used to evaluate the effectiveness of assistance programs.[8,9] Knowledge of disease patterns can inform clinical practice and guide resource allocation decisions. Finally, this information may be useful in designing training programs and orienting expatriate personnel. This paper reports our experience with epidemiologic surveillance of infectious diseases in the Site 2 South encampment for Cambodian refugees on the Thai-Cambodian border.

Methods

Following the Vietnamese invasion of Cambodia in 1979, there was a large influx of Cambodian refugees into camps in Thailand. These refugees were physically, mentally, and nutritionally exhausted after nearly a decade of war and four years of hardship under the Khmer Rouge. Several reports have described the health conditions in these early camps.[10–12] Ten years later there are still approximately 350,000 refugees in eight camps along the Thai-Cambodian border. Site 2, home to over half these refugees, is divided into North and South. Site 2 South has a population of approximately 70,000, or roughly 20 percent of the border refugee population.

The age distribution of Site 2 South is skewed toward the very young. Twenty-three percent of the population is under 5 years of age, and 43 percent is under 15.[13] The camp is severely overcrowded, with only 33 sq.m./person including public lands.[14] There is no ground water in Site 2, requiring that water be brought long distances by truck at considerable expense and resulting in a chronic shortage of water for personal hygiene. The average water ration is only 20 liters/person/day, significantly below the ideal of 100 liters/person/day recommended by the World Health Organization.[15] There is no running water, and the sewer system consists of open ditches between rows of houses. In the dry season these sewers are stagnant pools of waste. In the rainy season they quickly overflow, flooding nearby houses.

The population is totally dependent on external food supplies. The acute malnutrition rates in children under age 5 years, which were very high (>13 percent) in the acute phase of the refugee crisis, had stabilized at approximately 5 percent by 1985.[15] The prevalence of chronic malnutrition (stunting), however, remains high.[13] The diet consists primarily of rice and canned fish. The United Nations World Food Program supplies a food basket calculated to supply sufficient protein and calories. It is common, however, for camp residents to barter away some of their food aid on the black market, gaining variety at the cost of nutritional value. The persistence of significant malnutrition despite the provision of adequate protein and calories arises in part from this use of rice as the primary market exchange commodity; a phenomenon exacerbated by severe under-employment.

Humanitarian assistance for these refugees is provided through the UN Border Relief Operation (UNBRO), which supports and coordinates several voluntary agency health service programs in the camps. The American Refugee Committee has the responsibility for providing curative health services for Site 2 South; their hospital and two

outpatient clinics are the only curative health facilities serving Site 2 South. Maternal child health services, including antenatal screening, routine immunizations, and growth monitoring, are provided by a separate voluntary agency and are not covered by this report.

The hospital has dirt floors and lacks electricity or refrigeration. There are five wards: adult medicine, surgery, pediatrics, obstetrics, and a feeding center for severely malnourished children. During the year described by this report, the hospital had an average daily census of 223 patients. All wards are staffed and supervised by Cambodian health workers, nurses, midwives, and medical assistants. The expatriate staff, consisting of three nurses, two doctors, and a midwife, serve primarily as consultants and teachers. Laboratory facilities are limited to malaria smears, ova and parasite examinations, Gram and Acid Fast stains, hand-spun urinalyses, and colorimetric hemoglobin determinations. There are no chemistry, serology, or microbiologic culture facilities available. A mobile radiologic facility is available one morning a week.

A Health Information Office was developed by the American Refugee Committee to coordinate epidemiologic surveillance and investigation. This office was staffed by Cambodian and expatriate epidemiologists working closely with hospital and outpatient clinic staff, community leaders, and community service providers. The responsibilities of the epidemiologists included: collection of demographic and vital statistics data, administration of a reportable disease surveillance system, compilation of hospital and outpatient discharge diagnoses, outbreak investigation, and facilitation of clinical studies. The office also organized community health education campaigns and served as a source of information for the many programs involved in health promotion activities in Site 2.

Vital Statistics

Demographic data, obtained from the Cambodian camp administration, were derived from a family registration system maintained for the purpose of distributing relief materials. Monthly figures reflected population changes resulting from births, deaths, in-migration, and out-migration. This information was used as the basis for vital statistics. The receipt of additional relief supplies served as a powerful incentive to complete birth registration. Monthly consultations with the Buddhist monastery operating the camp's only crematorium, and the Khmer Moslem Association, served as a mechanism for death verification. Names and ages of deceased individuals were recorded, but reliable information concerning the cause of deaths occurring outside the hospital was typically unavailable. This method of death ascertainment was generally complete; however, some underreporting of neonatal deaths may have occurred because of the occasional practice of burying very young infants.

Reportable Diseases

The Health Information Office also administered a program to allow the prompt identification of diseases requiring immediate public health interventions: cholera, diphtheria, tetanus, measles, pertussis, encephalitis, dengue hemorrhagic fever, rabies, polio, typhoid, meningococcemia/meningitis, and sexually transmitted disease. The occurrence of any of these conditions was to be reported to the office within 24 hours, along with atypical presentations of more common diseases (e.g., the occurrence of malaria in a child). Contacts of incident tuberculosis and leprosy cases were investigated by a separate program. Given the extremely high prevalence of tuberculosis in Southeast Asia, a comprehensive program for the management of this disease had been developed previously, and is reported elsewhere.[16]

Hospital Discharge Data

At the time of hospital discharge a senior Cambodian medical assistant or midwife, in consultation with an expatriate health professional, recorded a discharge diagnosis. This diagnosis was entered into a log book in each ward, along with the patient's age, sex, name, and address. Precarious security conditions and emergency camp relocations have prevented the development of a permanent medical record system. Hence, the ward log books provided the only data available for retrospective analysis. Diagnostic accuracy and complete reporting were encouraged by random review of charts by clinical supervisors. Unfortunately, the volume of patients seen in the outpatient facilities (average monthly visits >18,000) prohibited complete recording of outpatient diagnoses. On Monday of each week all outpatient diagnoses were recorded and reviewed. During disease outbreaks, the office attempted to identify all outpatient cases, conducted home visits, and was involved in public educational campaigns targeted at curtailing the spread of disease.

Analysis

The results reported below were drawn from the activities of the Health Information Office, June 1987—May 1988. Population figures for January 1, 1988 were used in the computation of age-specific mortality and hospitalization rates. Analysis of the monthly population totals indicated that the population increased steadily throughout the year, and that this mid-year estimate was within 1 percent of the actual annual population average. By applying proportions from 1988 UNBRO demographic data[17] to these population figures, estimates for specific age intervals were obtained.

Results

Vital Statistics

During the study year, 3,261 births and 256 deaths were reported. The estimated crude birth rate was 46.3 per 1,000 population, the crude death rate 3.6/1,000 population. The infant mortality rate (infant deaths/1,000 live births) was estimated to be 27.3. The estimated under-5 mortality rate (deaths in children under-5/1,000 live births) was 33.4. Both the infant and under-5 mortality rates can potentially be biased by migration. During the study year there was a net in-migration of 4,024 people; however, only approximately 5 percent of these new arrivals were children under-5.

Table 1 shows the age- and sex-specific mortality rates. In general, mortality rates were low and resulted primarily from infectious diseases. Mortality rates for males were greater than those for females in the under-5 and some adult age groups. The higher mortality in male children was largely attributable to prematurity, neonatal sepsis, and acute respiratory illness.

Analysis of the cause-specific mortality rates for adults revealed the excess in male deaths to be entirely attributable to violence or malaria. There were 11 deaths from falciparum malaria in men and none in women. Epidemiologic investigation of exposure history revealed that most cases of falciparum malaria occurred in persons who had recently been outside the camp. These were mostly men involved with military or market-related activities who were exposed to the malarial parasite in Cambodia and subsequently returned to

TABLE 1—Age- and Sex-Specific Mortality Rates for Site 2 South, Thailand, June 1987 through May 1988

Age Group (years)	Population		Deaths/1,000/year*	
	Male	Female	Male	Female
<1	2075	1755	28.9 (60)	18.2 (32)
1–4	6630	6377	2.7 (15)	1.6 (10)
5–14	6953	7321	1.3 (9)	1.0 (7)
15–24	6702	4825	1.6 (11)	1.7 (8)
25–34	7992	6850	1.1 (9)	1.6 (11)
35–44	3046	3611	3.3 (10)	2.2 (8)

the camp for treatment. There was no evidence of sustained malarial transmission in the camp.

Reportable Diseases

An outbreak of dengue hemorrhagic fever in the summer of 1987 demonstrated the importance of maintaining a reportable disease surveillance system. This disease is a relatively rare, but potentially life-threatening complication of dengue. In 1987 there was a large outbreak in Thailand, with over 63,000 cases reported from 60 provinces in six months.[18] Cases began appearing in Site 2 in May 1987. Figure 1 plots the course of this outbreak in Site 2 South. The reportable disease system allowed the Health Information Office to quickly identify the first cases of the outbreak.

Prompt efforts to control the Aedes mosquito vector included pesticide spraying of houses bordering those of index cases, larval control efforts, and an extensive community education program. The latter included "dengue day" on which the primary school children were given the day off to collect larvae in competition for prizes. The combined effect of these efforts was to plateau the incidence of dengue hemorrhagic fever in the camp.

Only two cases of tetanus were reported, and no cases of pertussis, diphtheria, measles, or polio. The Health Information Office identified six isolated cases of meningococcal illness and promptly located and treated household and clinical contacts with antibiotic prophylaxis. No outbreaks of meningococcal illness occurred.

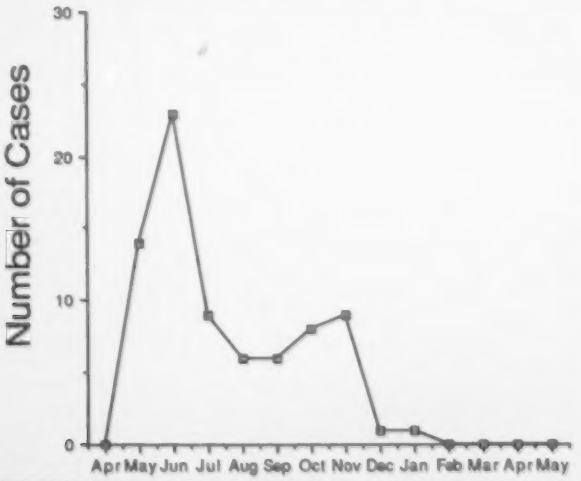

FIGURE 1—Presumed Cases of Dengue Hemorrhagic Fever in Site 2 South: 1987–88

The Health Information Office was also involved in the control of rabies, which is endemic in the dog population of Thailand. In October 1987, a dog in Site 2 was found to have rabies, confirmed by examination of the brain at the Science Division of the Thai Red Cross Society in Bangkok. Dogs that had bitten one or more persons and were stray, unwanted, or died during the period of observation were submitted for pathologic examination. Approximately 30 percent of dog brains submitted for pathologic analysis over the next several months were confirmed to have rabies. An investigation by the office revealed that few people sought medical attention for dog bites. The office began an extensive community education effort emphasizing the importance of post-exposure immunization. In October 1987, only four people were seen for treatment of dog bites. Beginning in November, the number of visits increased to approximately 30 per month and stayed at that level.

The Health Information Office also conducted a community survey to assess the dog population in the camp. It was determined that the dog population was comprised of mostly pet animals. Less than 20 percent of bites were traced to stray dogs, justifying an animal vaccination campaign. In the year following this campaign, none of the suspect dogs submitted for pathologic examination were found to have rabies.

Hospital Discharge Data

The vast majority of pediatric admissions were for acute infectious diseases: acute respiratory illness, skin infections, otitis media, and diarrheal disease (Table 2). Continuous monitoring of hospital discharge diagnoses provided definition of the seasonal variation of infectious diseases in the camp. Acute respiratory illness and diarrheal disease were most common in the rainy season (June—September). Skin infections were common throughout the year.

Monitoring of hospital discharge diagnoses also facilitated the early identification of outbreaks of these common pediatric illnesses. For example, there was an outbreak of acute respiratory illness in August and September. At the peak of the epidemic, the outpatient clinics, in Site 2 South saw 1,361 cases of pneumonia in a 17-day period. Most cases

TABLE 2—Hospital Discharge Diagnoses—June 1987 to May 1988

Diagnosis	Hospitalization Rate* Cases per 1,000 per year	Proportional** Morbidity (%)
Children (<15 years)		
Acute Respiratory Illness***	45.22 (1445)	34.3
Skin Infections	28.91 (924)	21.9
Otitis Media	9.33 (298)	7.1
Diarrheal Disease	8.58 (274)	6.5
Other	41.01 (1276)	30.3
Adults		
Prolonged Fever	94.27 (3623)	55.1

Falciparum Malaria	7.49 (288)	4.4
Urinary Tract Infection	6.45 (248)	3.8
Other	40.32 (1551)	23.6

*Number of cases in parentheses.
**Percent of hospitalized cases.
***Predominantly pneumonia, bronchiolitis, and croup.

occurred in infants or young children. Clinically, these children had diffuse pulmonary rales, with occasional wheezing. Chest X-rays performed in severe cases revealed diffuse interstitial pneumonia. A viral etiology was presumed on the basis of this information. Antibiotics were used conservatively and children were carefully observed for signs of hypoxia.

A large outbreak of diarrhea was seen in December and January. Almost all cases occurred in children under two years of age, with 56 percent of the cases occurring in infants. A spot map of cases failed to reveal any specific foci of infection. Chlorine levels in the water supply were found to be adequate to prevent microbiologic contamination. Clinically, children were afebrile and had watery, non-bloody diarrhea. This was presumed to be a rotaviral outbreak and efforts focused on the education of mothers in the preparation and use of oral rehydration therapy.

The majority of adult hospital admissions were also for acute infectious diseases. The most common diagnoses were "prolonged fever," skin infections, falciparum malaria, and urinary tract infections (Table 2). The term "prolonged fever" designates a collection of infectious diseases that are not easily distinguished with the diagnostic facilities available at Site 2. It is applied when the patient has 48 hours of documented fever >38.5 C, three negative malaria smears, and no signs or symptoms suggesting localized infection. Occasionally the clinical presentation is precise enough to allow a specific diagnosis, such as scrub typhus or typhoid fever, to be made. More often the patient is treated empirically and the discharge diagnosis is simply "fever of unknown origin." Analysis of the monthly discharge diagnoses of "scrub typhus" and "fever of unknown origin," however, showed an inverse relationship, suggesting considerable variation in the convention used for assigning these diagnoses.

There was no clear seasonal variation in the incidence of prolonged fever, skin infections, or urinary tract infections. Falciparum malaria occurred principally in November through January. These are the months following the rainy season during which men leave the camp to resume fighting in Cambodia.

Discussion

The demographic indicators in Site 2 South reveal some of the anomalies of long-term refugee camps. The crude birth rate is very high and comparable to that seen in the least developed countries.[19] On the other hand, the crude death rate is extremely low; lower than even in the most developed countries. (For comparison the US crude death rate is 9.) This reflects an age distribution skewed toward the very young and possibly the ready access to effective health services. Furthermore, the residents of long-term refugee camps are survivors. The more vulnerable members of a refugee population often perish during forced migration or the emergency phase of a relief effort.

The estimated infant and under-five mortality rates are middle range and comparable to those seen in countries such as Korea and Panama.[19] They were lower than the figures reported for Thailand (infant mortality rate = 41, under-five mortality rate = 53), despite the fact that the level of health care in Site 2 is designed to be comparable to that available in surrounding Thai communities. The geographic localization of the population, the greater intensity of health services, and the absence of financial barriers make this care much more accessible, however.

The ability to accurately characterize the demographics of a refugee population is important for optimal planning of humanitarian assistance efforts. For example, the high birth rate and low death rate in Site 2 indicate that, even without new arrivals, the population will expand at over 4 percent a year. Given the already overcrowded conditions in the camp, and the ill effects of this overcrowding on physical and mental hygiene, long-range planning must include identifying more land on which to shelter this population. These data also underscore the need for effective family planning efforts as part of an overall program for maternal and child health. Analysis of mortality trends can identify vulnerable subpopulations and indicate specific diseases requiring control or surveillance.

The importance of maintaining a reportable disease system that can readily identify outbreaks of illness requiring immediate public health intervention is essential in the overcrowded environment of a refugee camp. This is well illustrated by the Health Information Office's experience with the 1987 dengue hemorrhagic fever outbreak. While it is impossible to know what the course of this outbreak would have been without intervention, the large number of cases seen in nearby urban areas of Thailand, where disease control efforts were more difficult to implement, suggests the office's activities may have averted a much larger outbreak.[18] The experience of the Health Information Office in confronting rabies in the dog population of Site 2 demonstrates the role of such an office in coordinating a community response to a serious public health threat.

The successful provision of health services in a long-term refugee camp requires a strong community orientation. The training of refugee health providers and the briefing of expatriate health professionals must emphasize the public health context within which patients develop illness. The use of simple methods of epidemiologic surveillance and investigation can greatly facilitate the development of this perspective by documenting geographic, seasonal, and epidemic patterns of disease in the community. In an environment lacking the facilities for laboratory confirmation, therapy is often administered empirically based on the clinician's "best guess" as to the likely etiology. Consequently, clinicians aware of the epidemiologic patterns of disease in the community are better equipped to provide optimal care to the individual patient. The regular monitoring of hospital and outpatient discharge diagnoses by the Health Information Office allowed prompt characterization of disease outbreaks, as well as long-term or seasonal trends.

There has been little experience with epidemiologic investigation of non-infectious diseases in the camp. Occasionally outbreaks of illness have been traced to toxic ingestion of plants or black market medications. Recently, monitoring of hospital discharge data led to the recognition of a steady increase in the number of patients with trauma. Further investigation revealed a dramatic increase in suicide and domestic violence rates, symptomatic of the growing crisis in mental health in Site 2.[20] These are late signs, however, and not adequately sensitive for surveillance activities. As experience is gained, the use of simple epidemiologic methods will be extended to surveillance and investigation of non-infectious and chronic diseases, such as hypertension and cervical cancer.

In the last several decades, the world has seen ever-growing numbers of refugees. Increasingly these refugees are

becoming "long-stayers", living in subsistence camps for indefinite time periods. As the nature of refugee environments changes, the providers of assistance must mature and learn from their experiences. Unfortunately, refugee situations are often dominated by well-intentioned, but short-term, poorly prepared personnel operating in duplicative and loosely coordinated efforts.[1,3,10] Refugee health care should not be a hobby. It requires the coordinated efforts of refugee and expatriate health planners and providers sensitive to the public health needs and resource scarcities of long-term refugee camps. Our experience demonstrates that epidemiologic surveillance and investigation have an important role in shaping the clinical and public health response to infectious disease in these camps.

Child Vaccine Injury Claim Deadline is October 1

Health and Human Services Secretary Louis W. Sullivan has issued a reminder that the deadline is October 1, 1990 for a certain class of claimants who are eligible to use the recently authorized National Vaccine Injury Compensation Program. The program, which went into effect October 1, 1988, is intended to serve as a faster and less expensive procedure than a civil suit for resolving claims for certain vaccine-related injuries. Using this no-fault system, petitioners do not need to prove that those who manufactured or administered the vaccine were at fault. They must prove only that the vaccine is related to the injury. The federal program provides compensation to individuals who suffered injuries associated with one of the following vaccines: diphtheria and tetanus toxoids and pertussis vaccine (DTP); measles, mumps and rubella vaccine; oral polio vaccine; inactivated polio vaccine.

For injuries that occurred before October 1, 1988, claimants must file by October 1 of this year to use this program. Although claimants may not use the program if they file later, they still may pursue their claims in civil court. For injuries occurring on or after October 1, 1988, claimants must file within certain periods prescribed by the National Childhood Vaccine Injury Act of 1986 as amended.

As of April 5, 1990, some 263 petitions have been filed, 254 of which stemmed from injuries that occurred before October 1, 1988. Sixty awards totaling $31.5 million had been made as of April 5 under this program, with amounts ranging from $86,000 to $2.8 million.

For persons seeking information on the National Vaccine Injury Compensation Program, the Health Resources and Services Administration (HRSA) operates a toll-free hotline. The number is 800/338-2382.

Physician Breach of Patient Confidentiality among Individuals with Human Immunodeficiency Virus (HIV) Infection: Patterns of Decision

JUDITH A. SCHWARTZBAUM, PHD, JOHN R. WHEAT, MD, MPH, AND ROBERT W. NORTON, PHD

Abstract: To determine whether the sex, race, or sexual preference of a patient infected with immunodeficiency virus (HIV) influences a physician's decision to breach patient confidentiality, Tennessee primary care physicians were mailed a questionnaire containing a case study in which an HIV-infected patient presented a risk to a third party. Eight different descriptions of the sex, race, and sexual preference of the hypothetical patient were distributed randomly among the physicians, one description to each physician. The physicians were asked to decide whether to maintain confidentiality, notify the health department, or inform the patient's partner. Responses of 199 White male physicians were analyzed using an unconditional saturated logistic regression model. The odds ratios for these physicians saying they would send the patient's antibody status to the health department extend from 18.4 (95 percent confidence interval: 1.3, 260.1) for Black homosexual males to .5 (95 percent CI: 0, 11.5) for White homosexual females. The odds ratios for White male physicians saying they would inform the patient's partner range from 7.5 (95 percent CI: .8, 69.2) for Black heterosexual males to 1.0 (reference category) for Black homosexual females. The results suggest that when physicians decide to protect a third party by breaching an HIV-infected patient's confidentiality, their decision may be influenced in some cases by the race, sex, and sexual preference of the patient. (*Am J Public Health* 1990; 80:829–834.)

Introduction

One of the perceived ethical dilemmas associated with the acquired immunodeficiency syndrome (AIDS) epidemic is whether a physician should breach the confidentiality of a patient infected with the human immunodeficiency virus (HIV) to inform a third party at risk of infection from the patient but unaware of that risk. The American Medical Association has recommended that "if persuasion fails, the authorities should be notified; and if the authorities take no action, the physician should notify and counsel the endangered third party."[1] In this statement and similar statements[2,3] and discussions[4,5] of the policy of third-party protection, the assumption is that the demographic characteristics or sexual preference of the patient and third party are not relevant and that implementation of the policy is independent of the patient's identity. Kelly, *et al*,[6,7] have shown that AIDS patients are stigmatized by physicians. Because the policy of third-party protection requires that the physician judge the degree of danger presented by an HIV-infected patient to a third party and because that judgment could be influenced by social factors, we extended the work of Kelly, *et al*.[6,7] The purpose of our research was to evaluate the effect of a patient's demographic characteristics and sexual preference on a physician's decision to breach an HIV-infected patient's confidentiality to protect a third party.

Methods

Sample

A stratified random sample of 628 practicing primary care physicians was identified[8] from a population of 2,804 primary care physicians practicing in Tennessee in 1986. The strata used were specialty (family practice, general practice, obstetrics and gynecology, or internal medicine) and size of the community in which the physician practiced (urban or rural). Randomization was successful so that the distributions by specialty and community size observed in the sample were similar to those observed in the population. Both the sample and the population consisted of approximately 27 percent family practitioners, 15 percent general practitioners, 20 percent obstetricians and gynecologists, and 40 percent internal medicine specialists. Rural physicians constituted approximately one-third of both of the sample and the population. Each physician in the sample was mailed a questionnaire, with instructions to respond anonymously. To improve the response rate, a second questionnaire was sent to the entire sample, with instructions to ignore the second mailing if the first questionnaire had been returned. The combined response rate to the two mailings was 37.1 percent (233 questionnaires returned). Besides sending questionnaires, further efforts to contact individual nonrespondents could not be made due to the anonymity of the respondents.

Questionnaire

The questionnaire elicited information about the physician's demographic characteristics, knowledge of HIV infection and AIDS, and attitudes toward individuals infected with HIV. One of eight variations of the following description of a hypothetical patient, based on the work of Kelly, *et al*,[6,7] was presented to each physician: "John (Joan) is a 30-year-old Black (White) heterosexual (homosexual) male (female) who tested positive for HIV by the ELISA antibodies test and confirmed by the Western Blot test. He (she) has not been getting along with his (her) partner. He (she) has asked you not to tell her (him, i.e., the partner) the results of the test because he (she) believes that the knowledge would complicate matters." The subject was described as one of the eight possible combinations of sex, race, and sexual preference (for example: Black homosexual female) until the eight possible combinations of sex, race, and sexual preference were exhausted. The eight vignettes, identical except for the description of the hypothetical patient, were distributed randomly among the 628 physicians. The algorithm for randomization was the same for the first and second mailings so that each physician received a second questionnaire with a description of the same hypothetical patient as was in the first. Each of the eight vignettes was followed by these progressively intrusive five statements (the first of the five

© 1990 American Journal of Public Health 0090-0036/90$1.50

statements was intended to infringe on the patient's privacy the least and the last statement the most):

1. The knowledge of the antibody status would remain between my patient and me.
2. I would attempt to persuade the patient to inform any partners who might be infected.
3. The antibody status, but not the name, would be reported to the health department.
4. The name of the person and the antibody status would be reported to the health department.
5. If the person would not inform any partners who might be infected, I would attempt to do so if the person identified them.

Physicians were asked to indicate which of these statements would characterize their actions. More than one selection was permitted.

Analysis

Of the 233 respondents to the questionnaire, 11 were not considered for the analysis because they did not report the action they would take. If a physician indicated more than one decision, the decision that most violated the patient's privacy was used as a dependent variable in the analysis. The responses of the three physicians who said that the knowledge of the patient's antibody status would remain confidential were combined with the responses of the 53 physicians who said they would try to persuade the patients to inform their partners. We used unconditional logistic regression[9] to compare the hypothetical patients' characteristics among the physicians' decisions. The dependent variable for three separate models was coded "0" if the physician would maintain patient confidentiality or persuade the patient to inform his or her partner. The dependent variable was coded "1" in these three situations: (1) if the physician would notify the health department of the patient's antibody status (the first model) or (2) if the physician would provide the health department with the patient's antibody status and name (the second model) or (3) if the physician would inform the patient's partner (the third model). The independent variables were the hypothetical patients' sex, race, and sexual preference. Also included in each model were the potentially confounding variables: physician age, year of graduation from medical school, physician specialty, and the urban or rural location of each physician's practice. The change in estimate criteria[10] was used to decide whether to retain the confounding variables in the final models.

In a second set of three logistic regression models, the independent variables were represented by seven dummy variables corresponding to seven of the eight combinations of sex, race, and sexual preference of the hypothetical patients. The category of Black homosexual female was used as a reference category and therefore not represented by a dummy variable. The category of Black homosexual female was selected as a reference because doing so made most of the odds ratios positive and therefore easier to interpret. These three regression models were also adjusted for confounding using the change in estimate criteria.[10]

In addition to including confounding variables in the regression models, confounding was addressed by assigning the descriptions of the hypothetical patients at random and by restriction of the regression analysis to White male physicians. The prevalence odds ratios presented in this paper are based on a cross-sectional survey and are therefore not estimates of relative risks.

Finally, to determine whether the physician's age, year of graduation from medical school, specialty, residence, knowledge of HIV infection and AIDS, and attitude toward individuals with AIDS modified the effect of race on the ethical decision, we used logistic regression models containing race-physician characteristic interaction terms.

Results

The distribution by specialty and location of practice of the 222 responding physicians (Table 1) was similar to that of the 628 physicians in the sample. Because half the questionnaires sent to the physicians described White hypothetical patients, half described Black, half described homosexuals, and so on, lack of response bias would be suggested by the return of questionnaires in the proportions in which they were sent. Of the returned questionnaires, 50 percent described female patients, 49.1 percent described Black patients, and 49.6 percent described homosexual patients. Further, each of the eight patient descriptions constituted approximately 12.5 percent of the sample of the returned questionnaires. To eliminate the physician's sex and race as sources of confounding, the subsequent analysis was confined to the 199 White male physicians in the sample.

Table 2 shows the physicians' characteristics associated with each type of hypothetical patient. While the relatively small numbers of observations in each category show some variation, there appear to be no systematic patterns of association. Similarly, Table 3 illustrates an unexpected consistency of physician age across the different decisions.

The unadjusted percentages of decisions for each type of hypothetical patient are shown in Table 4. The range of the percentage of physicians who said they would maintain the patient's confidentiality varies from only 8.7 percent for Black heterosexual males to 44.4 percent for Black homosexual females. Black males and Black heterosexual females were each associated with a relatively high percentage of physicians who said they would report their antibody status to the health department (17.4, 21.4, and 17.4 percent Black

White homosexual male	7	(29.2)	2	(8.3)	7	(29.2)	8	(33.3)	24
White heterosexual female	8	(29.6)	2	(7.4)	11	(40.7)	6	(22.2)	27
White heterosexual male	7	(26.9)	1	(3.9)	11	(42.3)	7	(26.9)	26
Total (%)	56	(28.1)	21	(10.6)	78	(39.2)	44	(22.1)	199

heterosexual males, Black homosexual males, and Black heterosexual females, respectively). Physicians said they would directly inform the partners of White homosexual males more often than they would individuals in other categories. The overall association between the hypothetical patients' characteristics and the physicians' decisions was not statistically significant ($\chi^2[21] = 20.2$, $p = .51$). Because the data were sparse, a Monte Carlo estimate of the exact *p*-value was run.[11] The estimated *p*-value was identical to the large sample *p*-value.

The ratios odds shown in Table 5 represent the results of three separate logistic regression models. In each of these models, physicians who said they would maintain the patient's confidentiality are compared to those who made one of the other three decisions shown in the column headings in Table 5. The odds for physicians saying they would send the antibody status of Blacks to the health department are 10.7 times (95 percent CI: 2.2, 52.0) those for saying they would send the antibody status of Whites. Males, Blacks, and heterosexuals have odds ratios greater than 1.0 for each of the three comparisons.

TABLE 5—Influence of Hypothetical Patient Category on White Male Physician's Decisions

Patient Category	Would Report Antibody Status		Would Report Name		Would Inform Patient's Partner	
	Odds Ratio	(95% CI) (n = 77)[a]	Odds Ratio	(95% CI) (n = 134)	Odds Ratio	(95% CI) (n = 100)[b]

a) Adjusted for physician speciality, year of graduation from medical school, and location of practice. Four missing values for specialty excluded from the analysis.
b) Adjusted for physician specialty. Three missing values for specialty excluded from the analysis.

To see if the average effects (e.g., Black) shown in Table 5 were masking the modifying effects of the patient's sex, race, and sexual preference on one another, we ran a second set of regression equations using dummy variables to represent seven of the eight categories of patient sex, race, and sexual preference (Table 6). The category Black homosexual female was selected as the reference category because of the high percentage of physicians who said they would maintain confidentiality in this category (44.4 percent, Table 4). Using Black homosexual females as a reference category made most of the odds ratios greater than 1.0 (Table 6). The odds of White male physicians saying they would report the antibody status of Black homosexual males, as opposed to maintaining their confidentiality, were 18.4 times (95 percent CI: 1.3, 260.1) those of saying they would report the antibody status of Black homosexual females (Table 5). Considering the small sample size, the magnitude of the odds ratios (OR) for reporting the antibody status for Black heterosexual males (OR 10.7, 95 percent CI: .7, 192.4) and Black heterosexual females (OR 9.3, 95 percent CI: .7, 132.1) should also be noted. When the patient was described as a Black heterosexual male, the odds of physicians saying they would report a patient's name to the health department (OR 8.0, 95 percent CI: 1.3, 50.0) or inform a patient's partner (OR 7.5, 95 percent CI: .8, 69.2) were highest. The odds of informing the partners of White homosexual males were 4.8 (95 percent CI: .7, 30.8) times the odds of informing the partners of Black homosexual females.

The analysis of the modifying effects of the physicians' characteristics on the race of the patient showed that family practitioners said they would send the names of Blacks (OR 19.1, 95 percent CI: 2.5, 143.9) to the health department more often than they would send the names of Whites (OR 1.0, reference). None of the other patient characteristics that we examined (e.g., age, location of practice, knowledge of AIDS) appeared to modify the influence of the patient's race on the physicians' decisions.

If the physician indicated more than one decision, preceding analyses used the physician's decision that most infringed on the patient's privacy as the dependent variable. To determine whether the patient's characteristics influenced the progression of the physicians' decisions from less to more intrusive, we compared the responses in which physicians indicated more than one decision (n = 120) with those in which physicians indicated they would directly report the patient (n = 23). Physicians more often said they would attempt to persuade women to inform their partners before intruding on their privacy (OR 2.5, 95 percent CI: .9,6.8) than they would men (OR 1.0, reference).

We could not evaluate the importance of the characteristics of the hypothetical partner in predicting the physicians' decisions because the assumed characteristics of the partner were highly correlated with the sex-sexual preference interaction term; models including both the characteristics of the patient and of the hypothesized partner could not be estimated. Those models including the characteristics of the partner only yielded results similar to those containing the characteristics of the patient. Because the sex, race, and sexual preference of the hypothetical partner were not known and those of the hypothetical patient were, we modeled only the patient characteristics.

To estimate the degree to which being a White male (relative to being a Black male) would influence physicians' underreporting of HIV-infected patients to the health department, we calculated the population attributable risk.[9] We defined the outcome of interest as not being reported to the health department; we defined the exposure as being a White male. Using the data in Table 4, the estimated cumulative incidence of physicians saying they would not report White

TABLE 6—Influence of Hypothetical Patient Category on White Male Physicians' Decisions

Patient Category	Would Report Antibody Status		Would Report Name		Would Inform Partner	
	Odds Ratio	(95% CI) (n = 77)[a]	Odds Ratio	(95% CI) (n = 134)	Odds Ratio	(95% CI) (n = 100)[a]
Black homosexual female	1.0	(Reference)	1.0	(Reference)	1.0	(Reference)
Black homosexual male	18.4	(1.3, 260.1)	1.5	(.4, 6.6)	4.2	(.7, 27.1)
Black heterosexual female	9.3	(.7, 132.1)	1.5	(.4, 6.6)	2.1	(.3, 15.6)
Black heterosexual male	10.7	(.7, 192.4)	8.0	(1.3, 50.0)	7.5	(.8, 69.2)
White homosexual female	.5	(.0, 11.5)	2.0	(.5, 3.8)	1.1	(.2, 5.7)
White homosexual male	.9	(.0, 20.1)	1.3	(.3, 5.9)	4.8	(.7, 30.8)
White heterosexual female	2.3	(.2, 35.2)	1.8	(.5, 4.0)	1.7	(.3, 2.3)
White heterosexual male	.7	(.0, 14.8)	2.1	(.5, 4.1)	2.3	(.5, 11.5)

a) Adjusted for physician specialty, 7 missing values excluded from the analysis. See footnote Table 5.

males to the health department was .40. The cumulative incidence of saying they would not report Black males to the health department was .23. If 33 percent of HIV-infected males are White,[12] then the percentage of HIV-infected males who would not be reported to the health-department because they are White is 20 percent.

Discussion

White male physicians' decisions to violate patient confidentiality to protect a third party were influenced in some cases by the race, sex, and sexual preference of a hypothetical patient. Presented with vignettes about hypothetical patients, these physicians said they would report Black homosexual and heterosexual men to the health department and Black heterosexual men to their partners more often than they would report hypothetical patients in the other categories. Black heterosexual women and homosexual men were also less likely to have their confidentiality maintained. Family practitioners said they would report the antibody status of Blacks to the health department more often than would practitioners in other specialties.

Although the response rate is low, the internal validity of the survey has not been compromised and may be better than it would have been had the survey not been anonymous. As noted in the results section, the questionnaires were returned in proportion to their distribution in the sample. As Greenland[13] points out, the equality of the proportion responding over the levels of the exposure variable is not sufficient to assure lack of response bias. Response bias could have occurred in this case if the physicians who would have said they would breach confidentiality had been more or less likely to have responded, depending on the description of the hypothetical patient they received. Since the description of the scenario occurred on the sixth page of the questionnaire, it is unlikely that the physician decision to return to the questionnaire depended on the characteristics of the hypothetical patient and even less likely that there were interactions among the decision to return the questionnaire, the characteristics of the hypothetical patient, and the physician response.

Another component of internal validity is information bias. It was to prevent information bias that the anonymous questionnaire was chosen, since we believed that questions about physician knowledge and ethical decisions could best be answered anonymously. This is the method used by Kelly, *et al*,[7] and we achieved a higher response rate than they did. While the proportion responding is an important criterion, the validity of a study should not be sacrificed merely to achieve a high response rate.

That the study is externally valid is suggested by the equality of the distribution of physician specialty and location of practice among the respondents to that of the sample. However, the respondents may differ from those who did not respond in ways that cannot be measured; what is important is that whoever these 222 respondents represent, some appear to be influenced by the sex, race, and sexual preference of the hypothetical patients when making an ethical decision. Even if the nonrespondents were completely impartial, the respondents constitute a large enough portion of the total sample to require consideration.

The fallacy of using statistical significance alone as a criterion for interpreting the results of observational studies has been discussed at length in this Journal.[14–18] Although there can be no question of the statistical significance of the odds ratios associated with Black homosexual and heterosexual males, one might question whether the borderline associations in the first and third column of Table 6 (having confidence intervals with lower bounds greater than or equal to .7 and less than 1.0) are meaningful. First, the borderline confidence intervals must be interpreted in the context of small sample sizes, multicollinearity, and the pattern of the odds ratios across the levels of the physician decisions. Of the five borderline confidence intervals, four are associated with a hypothetical patient who is Black. Because of the artifacts working against statistical significance, it would be improper to dismiss the borderline associations as uninformative. Most important, our results are consistent with the known stigmatization of Blacks,[19] more specifically of Black men, by Whites. It is in this context that our findings must be given serious consideration.

Whether the results can be attributed to prejudice or whether the different physician response patterns were motivated by consideration of the sources of HIV infection prevalent in the groups with which the hypothetical patients were associated cannot be determined from these data. Because Blacks who are infected with HIV are more likely to use intravenous drugs than are similarly infected Whites,[12] physicians may believe that they are less likely to be conscientious about informing their partners. Blacks are more often treated in the health department than are Whites[12]; therefore physicians who say they would send Blacks to the health department may merely reflect sociological reality rather than exhibit prejudice. However, saying they would send Black men to the health department more often than hypothetical patients in other categories is also consistent with racial prejudice.

Laumann *et al*,[20] found evidence for the underreporting of AIDS among middle class Whites. They suggest that the underreporting may be due, in part, to the diagnosis of Whites by private physicians, while Blacks are more often diagnosed by individuals directly associated with the health department. Our results are consistent with Laumann's findings and suggest one pathway for the underreporting of Whites. If accurate estimates of the number of individuals infected with HIV or diagnosed with AIDS are to be made, physicians should be made aware of this possibly unconscious bias in reporting.

Further research is needed to determine whether the observed patterns can be attributed to risk factors that are more prevalent among HIV-infected Black men (such as intravenous drug use) or with racial prejudice or both. Regional patterns of physician decision-making should be investigated, and the characteristics of physicians who make particular types of decisions should be identified. Because physicians may not be aware that their HIV-related ethical decisions are influenced by the characteristics of the patients, the results of such research can, in themselves, be educational and may also explain some of the patterns of underreporting of HIV-infected individuals.

US Organ Transplant System Called 'Effective and Efficient'

The United States now has a "defined organ transplantation system, operated through the Organ Procurement and Transplantation Network, that appears to be effective and efficient," stated Dr. Robert G. Harmon, Health Resources and Services Administration (HRSA) Administrator, in testimony on April 20 before Rep. Henry Waxman's Subcommittee on Health, US House of Representatives.

The OPTN is operated by the United Network for Organ Sharing in Richmond, Virginia which has received HRSA contract funds since 1986 for its development and operation. All clinical transplant centers, organ procurement organizations, and tissue typing laboratories involved in organ transplantation are participating members of the network. Dr. Harmon cited a number of "significant accomplishments" made during the developmental period:

- The number of multi-organ donors increased by 30 percent since 1985, from 2,120 to 2,753 a year;
- The donor kidney discard rate decreased from 12.5 percent in 1986 to the present 4.6 percent;
- The number of kidneys exported overseas decreased by 93 percent, from 258 in 1983 to 17 in 1989, making more kidneys available to patients in the United States;
- A single source of data on organ donors, transplant candidates and transplant recipients has been established; and
- Procedures are in place to develop policies designed to assure equitable access to donate organs.

The number of heart and liver transplants and transplant centers has grown rapidly in recent years. From 1984 to 1989:

- Liver transplants rose from 308 to 2,160;
- Heart transplants rose from 346 to 1,673; and
- Pancreas transplants rose from 87 to 413.

The number of transplant programs also rose markedly. From 1984 to 1989:

- Heart programs increased from 37 to 147;
- Liver programs increased from 24 to 79; and
- Kidney programs increased from 170 to 221.

Despite the growing number of transplants, the number of people waiting for donor organs continues to increase. Currently more than 20,000 people are waiting for an organ transplant. The number of donors decreased from 4,090 in 1988 to 3,993 in 1989.

Effect of Changing Patterns of Care and Duration of Survival on the Cost of Treating the Acquired Immunodeficiency Syndrome (AIDS)

GEORGE R. SEAGE III, MPH, STEWART LANDERS, JD, MCP, GEORGE A. LAMB, MD, AND ARNOLD M. EPSTEIN, MD, MA

Abstract: We performed a two-year cost of illness study of 240 AIDS patients (55 percent of all Massachusetts cases) diagnosed and treated at five hospitals from March 1984 through February 1986. Sociodemographic and clinical data as well as information on medical utilization were obtained from review of inpatient and outpatient hospital records.

The yearly inpatient cost per patient decreased by 28 percent from $38,369 in year one to $27,714 in year two. These changes were related to shorter lengths of stay (from 20.6 days to 16.8 days per hospitalization, mean difference of 3.8 days, 95% CI of the difference −.2, 7.8), and less costly hospitalizations (from $12,463 to $9,957, mean difference of $2,506, 95% CI of the difference $135, $4,877). The probability of hospitalization, however, was similar in both years. These patterns of care were still evident after controlling for transmisson category, race, site, mortality, insurance, age, gender, number and type of opportunistic diseases and time since diagnosis. Although the cost per patient per year decreased between years one and two, median survival increased by 70 percent (from 10 to 17 months). Hence overall estimated lifetime costs increased by 24 percent. (*Am J Public Health* 1990; 80:835–839.)

Introduction

As of December 1989, more than 100,000 cases of AIDS (acquired immunodeficiency syndrome) had been reported to the Centers for Disease Control (CDC).[1] It is estimated that there may be an additional 1.5 million people infected with the human immunodeficiency virus (HIV),[2] the virus that causes AIDS.[3–5] The CDC has projected that in the next three years, the number of AIDS patients may increase more than four-fold.[6]

Several studies examining the medical costs of treating AIDS have been performed, with lifetime medical care cost estimates ranging from $20,320 to $147,000 per patient.[7–16] Although these studies provide useful preliminary information, they suffer from a variety of deficiencies. Almost all of the studies to date have been based at single settings with small numbers of patients or have used the records of a single insurer. They have generally examined cross-sectional data over limited periods of time, hence were unable to measure changes in utilization over time. Temporal changes are important because medical and social treatment patterns may vary substantially for a newly discovered disease. In addition, previous studies have generally not included survival data which makes it difficult to estimate lifetime costs and have not provided information on the costs of treatment in relation to clinical characteristics.

This report describes a two-year study designed to address these issues. It includes data describing patterns of inpatient and outpatient medical utilization, survival and cost for patients with AIDS as well as changes in these patterns over the two-year period.

Methods

Selection of Patients

Study participants were selected by reviewing medical records at five major Massachusetts medical centers that care for patients with AIDS. Four Boston hospitals were selected because they provided care for the largest number of AIDS cases in Massachusetts; the fifth was selected because it had cared for the largest number of cases in the state outside of Boston. All persons receiving primary care for AIDS at one of the five study hospitals between March 1, 1984 and February 28, 1986, and who met the CDC criteria for AIDS[17] were included. Patients who met the 1986 CDC criteria for AIDS and did not receive their primary care at these institutions (those seen once for consult or only for therapeutic protocols) were excluded. The protocol for this study was approved by the Institutional Review Boards at all participating institutions.

A total of 240 cases were identified by the five medical centers, including 34 prevalent cases identified at the beginning (3/1/84) of the observation period and an additional 206 cases diagnosed during the two-year observation period. To assess completeness of patient identification, names of the study participants were phonetically coded by use of a Soundex code and compared with statewide AIDS surveillance records. The 206 incident cases represented 87 percent of the 236 cases that were diagnosed and reported to the AIDS surveillance program by the same hospitals and 55 percent of all AIDS patients reported to the state program during the two-year observation period. Due to concerns of confidentiality, we were not able to ask hospitals for records of the 30 patients that were discovered as having been reported to the surveillance program but not identified for this study. Hence we are unable to ensure that these 30 individuals were appropriate exclusions, i.e., diagnosed at the study site but recipients of primary care elsewhere. These 30 cases were similar in age, gender, transmission category, and presenting diagnosis to the 240 study subjects. Of the 240 cases, six cases (2.5 percent) were reported by more than one hospital and were credited for purposes of this study to the hospital in which the majority of utilization occurred; however, utilization from both hospitals was included in calculating overall costs.

Data Collection

Sociodemographic data (age, gender, insurance coverage, race) and clinical characteristics (opportunistic infection present at initial diagnosis, number of opportunistic infections developed during the study period, and risk factors for

AIDS) were obtained by reviewing ambulatory and inpatient hospital records at the participating institutions. Use of outpatient services including office visits and diagnostic tests was evaluated by reviewing outpatient medical records at four of the participating institutions during the two year study period (March 1, 1984 to February 28, 1986). Because of administrative difficulties, the fifth institution, which cared for 23 percent of the study cohort, was able to provide data on outpatient utilization only for the first year of the study. Thus the denominator was reduced for calculations of outpatient utilization during the second year of the study.

Data on hospital utilization in terms of length of stay (LOS) and hospital charges were obtained from the billing departments of the participating institutions. Hospital costs were then estimated by applying the Massachusetts Rate Setting Commission year-specific/hospital-specific charge/cost ratios. Total inpatient costs per patient were derived by adding to hospital costs inpatient physician fees estimated using the following algorithim: 1) first inpatient day consisted of one admission visit, one consult visit, and one routine visit; 2) for each subsequent day, one routine visit fee was added.

Costs for ambulatory care and hospital doctor visits were estimated by using 1984 Blue Cross and Blue Shield customary reimbursement rates for office visits and diagnostic tests at hospital settings.

Data Analysis

Calculating Overall Cost—We examined cost of hospital care and ambulatory costs as well as the combined cost in terms of mean cost per patient per year during each of the two study years. Since every patient did not receive care for a full 12 months (some were diagnosed prior to the study period and some died during the study period) we tabulated a cost per patient per month for all patients alive in a particular month. For each year we calculated a mean for all patient months and multiplied by 12 to arrive at an annualized estimate.

Analyzing Incidence of Hospitalization—A two-part analysis was performed to better understand the trends and predictors of hospital admission lengths of stay and costs. We first examined overall rates of hospital admission and analyzed their association with patients' sociodemographic and clinical characteristics. Each month a subject in the study was coded as a binary variable depending on whether or not he or she was admitted to the hospital. Since more than one admission within a month was unusual (1.8 percent) and the second admission was usually related to the same episode of illness, the incidence of "hospital admission months" closely estimates the incidence of hospitalization. Crude rate ratios based on this index were calculated for study year, age, gender, transmission category (homosexual male, intravenous drug user, other), race, time since diagnosis, mortality (whether or not the patient died during the particular month), payor status, and number and type of opportunistic diseases.[18] We defined time since diagnosis as a binary variable based on whether the month was either the first or second since diagnosis, or a subsequent month. We made this determination by examining univariate plots which showed that the first two months after diagnosis were associated with a much higher incidence of hospitalization; thereafter rates were relatively similar. Next we examined the predictors of hospitalization simultaneously, estimating the likelihood of hospitalization during each month with a logistic regression model. The adjusted rate of hospitalization per month was estimated and 95% confidence intervals (CI) were calculated by the method of Miettinen.[19] For grouped variables, a likelihood ratio test of significance was performed.[20] This allowed us to assess the difference in rates of hospitalization each year for patients with the typical clinical and sociodemographic characteristics in our overall study sample. The probability of hospitalization per year was estimated from the adjusted coefficient of the maximum likelihood.[20]

Analyzing Length of Stay and Cost of Hospitalization—The second part of the analysis employed two linear regression models to examine temporal changes in the adjusted average length of stay and the average cost per hospitalization for those hospitalized. Using analysis of covariance we examined differences in cost between years one and two controlling for age, gender, transmission category, race, time since diagnosis, mortality, payor status, and the number and type of opportunistic infections.[21] As explained above, in less than 2 percent of months patients had more than one hospitalization. In order to use study "months" as our denominator we treated multiple hospitalizations during a month as a single hospitalization, combining the length of stay and costs related to the multiple events. Hence, our estimates for the likelihood of hospitalization are slightly low and our estimates for utilization and length of stay once hospitalized are slightly high. We know of no reason why this should be biased temporally. Because the distribution of the dependent variable was skewed, we performed a logarithmic transformation of length of stay and cost per hospitalization to assess statistical significance.

Survival Analysis—To determine overall cost per patient, a Kaplan-Meier survival analysis was performed on the cohort to determine the median survival.[22] A test of significance of the survival distribution comparing patients diagnosed during year one with patients diagnosed during year two was performed with the generalized Wilcoxon-Gehan Statistic.[22] Patient status (living or dead) was ascertained as of January 1, 1987 from vital records and mortality status was recorded as either dead, with the month and year of death, or alive.

To estimate lifetime costs, costs per patient month were multiplied by the median months of survival.

Evaluation of Outliers—A possible concern was the role of potential "outliers," i.e., individuals with unusually long or costly hospitalization, which may be related to temporal changes in the treatment of AIDS patients. To evaluate the potential impact of outliers, we examined the prevalence of 1 percent and 5 percent (based on the entire study population) length of stay outliers by study year. We then repeated both the length of stay and cost per hospitalization analyses with the 1 percent and 5 percent outliers removed.

Results

Table 1 displays demographic and clinical characteristics of the study cohort. The large majority were homosexual or bisexual men (81 percent); 16 percent were entirely uninsured, 24 percent had Medicare/Medicaid. Only 14 percent of patients presented with an initial diagnosis other than Pneumocystis *carinii* pneumonia (PCP) or Kaposi's Sarcoma (KS); 54 percent had multiple opportunistic diseases during the study period. There were no significant differences in demographic and clinical characteristics of individuals by year of diagnosis (Table 1).

Overall Utilization

The average length of observation was 7.6 (SD 5.3 months). Of the 240 patients with AIDS, 204 (85 percent) were hospitalized at least once during the study period. Members of the cohort were hospitalized 469 times (mean ±

SD = 1.95 ± 1.8), with a mean length of stay of 17.3 (± 20.8) days (range 1–252). Mean cost per hospitalization was $10,868 (SD $12,813, Table 2).

Unadjusted medical care costs in year two were 28 percent lower than year one. Over 90 percent of these cost were related to inpatient utilization. Crude inpatient costs per patient per year were $38,369 in year one, compared with $27,714 in year two. Crude outpatient costs per patient per year were $2,706 in year one, compared with $2,215 in year two.

Rate and Predictors of Hospitalization

A stratified analysis of the rate of hospitalization showed that women, intravenous drug users (IVDU), Blacks, Hispanics, individuals who died, individuals on Medicare/Medicaid, and individuals at three of the five study sites were significantly more likely to be hospitalized. Individuals with only one opportunistic disease during the study period, or presenting with Kaposi's Sarcoma (KS) alone, were significantly less likely to be hospitalized during the study period.

When we examined age, study year, gender, risk, race, site, mortality, insurance, number and type of opportunistic diseases, initial diagnosis, and time since diagnosis simultaneously, we found that the number of opportunistic diseases, death during the study month, different categories of insurance status, time since diagnosis, and sites of care were predictors of hospitalization (Table 3).

TABLE 2—Overall Utilization during the Two-Year Study Period* (N = 240)

Description of Service	Mean ± SD	Range
No. of hospitalizations (N = 469)	1.95 ± 1.8	(0–10)
Length of Stay (days)	17.3 ± 20.8	(1–252)
No. of intensive care days	1.2 ± 5.0	(0–69)
Cost per hospitalization	$10,868 ± 12,813	($363–107,111)
No. of outpatient visits	7.0 ± 8.3	(0–60)
Cost per visit	$269 ± 307	($0–13,858)

*3/1/84–2/28/86

Temporal Changes in Utilization of Hospital Care

Table 4 shows the probability of hospitalization during each of the study years as well as the lengths of stay and the costs for hospitalization for those hospitalized. After adjusting for confounding variables, there was no important difference in rates of hospitalization between study years. However, once hospitalized, patients in year one had longer (3.1 days) and more costly ($2,432) lengths of stay.

Survival after AIDS Diagnosis and Lifetime Cost

Figure 1 contains the results of a Kaplan-Meier analysis of months of survival for two cohorts of patients, one cohort diagnosed in year one or earlier (n = 110) and the other diagnosed in year two (n = 130). Whereas individuals diagnosed in year one lived a median of 10 months after diagnosis those diagnosed diagnosed in year two lived a median of 17 months. We estimated lifetime hospital cost in each year as the product of unadjusted hospital cost and median survival. Although unadjusted hospital cost per year (inpatient and outpatient) decreased by 27 percent between year one and year two (from $41,075 to $29,929) (Table 2), estimated lifetime hospital cost increased by 23.8 percent (from $34,229 to $42,399).

Evaluation of Outliers

Interestingly, most of the observed temporal decrease in cost was related to the shorter length of stay and reduced cost for individuals hospitalized in year two. To evaluate the potential impact of outliers, we performed a test of significance of the prevalence of the 1 percent and 5 percent length

of stay outliers by study year. The prevalence of both 1 percent and 5 percent outliers was significantly greater during the first year of the study. We then repeated both the length of stay and cost per hospitalization analyses with the 1 percent and 5 percent outliers removed. In the reanalysis we found that length of stay and cost per hospitalization remained significantly higher during the first year of the study.

Discussion

Our results illustrate the importance of multiple factors that produce temporal changes in the cost of treating AIDS. These include changes in: patterns of treatment, length of patients' survival, and characteristics of the patient population. Our findings suggest that although the cost per patient per year may have decreased, overall lifetime costs may have increased because of improved survival.

In our population, there was little temporal variation in patients' clinical and sociodemographic characteristics. However, this is not likely to be true in the future. Regions of the country such as New York City and Massachusetts have demonstrated a recent increase in the incidence of AIDS among groups such as intravenous drug users.[23,24] Our analysis suggests that such characteristics may also be important predictors of hospitalization and associated cost.

While the median survival time in our study population was short (14 months), it must be kept in mind that all of the

patients in our study were diagnosed prior to March 1986. Our cohorts' median survival was slightly longer than that observed in New York City during a similar period of time.[25] We assume that much of the increase in survival among individuals diagnosed during the second year is due to wider recognition of complications and changes in treatment. However, we were concerned some component may be due to lead time bias, an earlier diagnosis of disease, in which case our estimates for the differences in survival by year may be exaggerated. In order to assess this possibility, we reviewed surveillance records of patients diagnosed at the five study sites during the two time periods. We evaluated the method of diagnosis (n = 240), number of symptomatic months before diagnosis (n = 163), and the ratio of T-helper lymphocyte count to T-suppressor count (T-cell subsets) for those patients in which T-cell evaluations were performed and reported (n = 51). We found no significant differences in these indices by year of diagnosis. Hence, we feel that our findings are not likely to be a result of lead time bias.

Individuals with AIDS require a substantial amount of health care resources. In our study the mean cost of medical care was $37,404 per patient per year. Most other estimates have been in the $40,000 to $70,000 range.[8–16] These large costs have obvious implications for national health policy. Assuming an average lifetime cost of $42,399 per patient, the 110,000 AIDS patients already diagnosed will already require medical care expenditures of over $4 billion. The economic burden is substantial and may present a particular problem for teaching and public hospitals, where patients with AIDS tend to be hospitalized. It must be kept in mind that we assessed the direct medical care costs associated with treating AIDS and did not measure the indirect, nonmedical costs of AIDS, which may be enormous.

Several methodologic issues should be noted. As with virtually all cost-of-illness studies, we assessed average medical costs which may overestimate the incremental, i.e., marginal, medical cost of treatment. On the other hand, our results represent an underestimate of the total medical cost of treating a person with AIDS. Although we believe that the five hospitals in the study were the major source of medical care for the patients in our study, some patients may have received additional care at other sites. In addition, this study was performed before the licensure of AZT (azidothymidine). The annual cost of therapy with this medication is approximately $8,000 per patient per year[26,27] and it can be expected to have a major effect on both earlier diagnosis and survival after diagnosis.[28,29] We believe that both the methodology and results of our study will form a baseline to which later utilization studies may be compared.

Future studies of the economics of AIDS need to incorporate not only the actuarial estimates of the cost of care, but also clinical and organizational factors as well as life expectancy. The unique nature of this disease and its tremendous social and economic burden make such monitoring essential.

The Impact of DRGs on Community-based Service Providers: Implications for the Elderly

JUANITA B. WOOD, PHD, AND CARROLL L. ESTES, PHD

Abstract: We investigated changes in community-based agencies following the implementation of the Medicare prospective payment system for hospitals utilizing DRGs (diagnosis-related groups). Data were collected in 1986 and 1987 from 771 community service providers. There were five major findings: 1) hospital discharge planners, nursing homes, and home health agencies experienced DRG effects before other types of community providers studies; 2) the "reach" of DRG impact is widespread; 3) providers report a change in clientele toward a heavier-care client; 4) the impact of DRGs affects the types of services agencies provide; and 5) community providers have experienced a decrease in their ability to refer their clients both to hospitals and to each other. (*Am J Public Health* 1990; 80:840-843.)

Introduction

A number of research studies have focused on the short-term effects of the Medicare Prospective Payment System (PPS), particularly in terms of the utilization and cost of hospital services.[1-9] A limited number of studies have also focused on the effects of PPS on post-hospital care, although these have generally given primary attention to home health care and other Medicare-reimbursed services.[10-17] There has been little documentation, however, on the effects of PPS on a broader range of community-based service providers and, by extension, on the elderly population they serve. This important, but understudied, area of care is addressed here.

PPS-related early hospital discharge changed patterns of post-hospital service utilization, affecting community agencies, individuals and families.[18-26] The adequacy of the community-based service system to respond to new demands, either in the form of demand for new types of services or increased intensity of existing services, raises questions of access for the older adult population needing those services. While this study explores DRG (diagnosis-related groups) impact from an agency perspective and records organizational changes that service providers report making, it is possible, nonetheless, to suggest some of the ways in which these organizational changes will affect clients.

Methods

The research question asks post-hospital care organizations how DRGs have affected their staffing, service provision, and the types of clients served.

Data Sources

Study data were drawn from several sources:

- telephone survey interviews with a probability sample of seven types of service providers conducted in Spring of 1986 and again in Fall of 1987;
- telephone interviews with state and local policy makers and representatives of major provider associations ("key informants") in the states studied, conducted in 1988;
- detailed case studies and in-person interviews in two study communities;
- secondary data obtained from a variety of sources, including the Area Resource File, Census data, and the National Nursing Home Survey of 1985.

Site Selection

Sample States. States and SMSAs (standard metropolitan statistical areas) were selected purposively to assure some geographic variability. Each of the five states in the sample (California, Florida, Pennsylvania, Texas, and Washington) was the most populous state in its federal administrative region. They had also been identified by the regional directors of the Administration on Aging in 1976 as having the most innovative and generous aging programs in their regions. The states selected assured some diversity of sociodemographic and state economic conditions, factors that have been shown in other studies to affect expenditures and utilization of long-term care services. Our assumption is that, if we find shortfalls or gaps in these states, we would expect that the situation is likely to be as difficult or more so in smaller, less urbanized states.

Sample SMSAs. The SMSA was selected as the geopolitical unit from which to sample provider organizations because such catchment areas better represent the referral, market and interorganizational system for long-term care services than does a single city or county. In all cases one or two of the top four largest metropolitan areas (exceeding a population of one million) in the state were included in the study: Miami and Tampa/St. Petersburg; Philadelphia and Pittsburgh; Dallas/Ft. Worth and Houston; San Francisco/Oakland and San Diego; and Seattle. The sample represents nine of the 11 largest metropolitan areas in the five sample states and nine of the 24 largest metropolitan areas in the nation.

Provider Sample. The sample of provider organizations was selected randomly using probability sampling techniques, and the directors of each, or their designees, were interviewed by telephone for 30 to 60 minutes. The survey instrument contained both close-ended and open-ended questions covering the topics of: organizational structure; staffing patterns; clientele; service patterns; budgetary sources; opinion questions on policy issues; and perceptions of DRG effects in specific areas. This article presents the responses to the questions on DRG impact.

The service provider sample is comprised of a total of 771 respondents, representing seven different service providers interviewed in 1986 and again in 1987. This combined data set consists of: 178 discharge planners, 166 home health

agencies, 166 nursing homes, 39 adult day care centers, 104 senior centers, 24 hospices, and 94 community mental health centers, rendering a total of 1542 interviews.

In 1986, respondents were asked to report on events and describe organizational changes occurring between 1984 and 1986 (to tap the immediate period of DRG implementation). In 1987, respondents were asked to report on events and changes occurring between 1986 and 1987. Thus, the data collected cover the period from 1984 to 1987.

Results

Five major findings emerged from the study (selected tables are in the text; further data may be requested from the authors).

- **First and Second Generation Effects.** In response to an open-ended question asking respondents to identify the policy that had most effect or impact on their organization during the time period studied, the policies that were most frequently nominated, in rank order, were DRGs and other Medicare policies (Table 1).

The types of DRG effects agencies described included increased demands as a result of earlier release of older hospital patients still needing some form of care. The other Medicare policies nominated were associated with reimbursement such as problems with fiscal intermediaries and inadequate reimbursement.

Table 1 also illustrates the lag time in reported DRG effect by different types of agencies. The "first generation" effects of DRGs (1984–86) were most immediately and directly experienced by hospital discharge planners, nursing homes, home health agencies and, to a much lesser degree, community mental health centers. In 1987, however, the percentage of these providers nominating DRGs as the most important policy affecting them declined, while adult day care centers and hospices reported being affected by DRGs for the first time.

While the one-fourth of adult day care centers reporting DRG effects is not large, the reason given for the impact, we believe, heralds an important trend. Adult day care centers reported that they were receiving more post-hospital patients referred from home health agencies after their Medicare benefits were exhausted, but before their care needs were met. This reason also explains the dramatic increase in the percentage of day care centers that reported being affected by other Medicare policies. At present adult day care services are paid for privately or by Medicaid, but not by Medicare. These centers believe the care they are now offering should be covered by Medicare as well.

- **The "Reach" of DRG Effects.** When we calculated the percentage of all providers reporting at least one type of DRG impact, we found that all seven types of providers reported being affected by DRGs in at least one of the following ways: types of clients served, services required or provided and/or referral patterns. The percent of providers reporting one or more types of DRG impact ranged from a low of 58 percent of senior centers to a high of 98 percent of discharge planners (table not shown). This is additional evidence that DRG effects were experienced not only by medical service providers but also by social service providers.
- **Change in Type of Client.** Providers were asked if they experienced changes in the types of clients they serve as a result of DRGs. As expected, the organizations most likely to receive patients directly following hospital discharge (home health agencies, hospices, and nursing homes) more frequently reported this type of DRG effect. Interestingly, however, even one-third of senior centers reported a change in clientele linked to DRGs (Table 2).

When asked to indicate *how* their clientele had changed, the predominant response across providers, was that clients were more frail, physically sicker and/or in need of more acute care services than in the previous study period. Overall, 60 percent reported this in 1986 and 57 percent in 1987.

- **Change in Services.** The increased tendency for clients to be heavier-care is also reflected in the responses to questions about DRG effects on services (Table 3).

Discharge planners differ from other providers in that their function is to assess and arrange for services needed by hospital patients upon discharge. Their most frequently mentioned service changes were in outpatient services and increases in the amount of discharge planning done by the hospital. For home health agencies, hospice programs, and nursing homes, the most frequently reported shifts in service were toward: more acute high-tech care; more skilled nursing; and more antibiotic intravenous therapy. Home health agencies reported this type of impact first (1984–86), while nursing homes and hospices reported more shifts of this type between 1986–87. Senior centers most frequently reported

providing increased information and referral services, and adult day care centers reported providing more direct supervision and more rehabilitative therapy. Community mental health centers reported case management was increased as were services for the chronically ill.

As an additional indicator of whether or not patients were being released with more medically related needs, a question was asked about changes in the units of service required as a result of DRGs. The majority of providers reported changes in the units of service now required by their clientele. For both years of the survey, the reported changes were in the direction of increased units of service required—either increases in the number of visits or increases in the length of time of care per patient.

- **Change in Referral Ability.** A substantial percentage of agencies reported change in their ability to refer clients to hospitals (Table 4). The most frequently reported change was an increased difficulty in referring clients from community service providers *to* hospitals due to stricter hospital admission policies making *both* admission and re-admission more difficult. This problem was reported more frequently in 1986 than in 1987, although a sizable proportion of providers were still reporting difficulty in 1987.

Not all providers were queried in both 1986 and 1987 about changes in their ability to refer to other community providers (all providers were asked in the 1987 survey). However, of the three types of agencies for which there are data for both 1986 and 1987, discharge planners and home health agencies were more likely to report changes in their ability to refer to other agencies in 1986 than in 1987. The proportion of adult day care centers remained virtually the same both years. The direction of the change reported was an increased difficulty in referring clients to other community agencies

Most disturbing is the number of discharge planners who reported changes in the direction of increased difficulty in referring their hospital patients to other agencies for both time periods of the survey. In 1986, 31 percent of all discharge planners interviewed (N=178) reported increased referral difficulty due to fewer resources and more difficulty in gaining admission to nursing homes. In 1987, that percentage increased slightly to 34 percent and was reported to be due to: more difficulty in obtaining homemaker/chore services, fewer resources available in general and longer agency waiting lists.

TABLE 4—PERCENTAGE OF AGENCIES REPORTING CHANGES IN ABILITY TO REFER TO HOSPITALS

Agency Provider Type	1986* %	N	1987** %	N
Hospice Programs	58.3	(24)	40.0	(20)
Community Mental Health	43.3	(90)	38.6	(88)
Home Health	35.7	(154)	25.5	(161)
Nursing Homes	30.5	(164)	25.9	(166)
Adult Day Care	20.6	(34)	18.8	(32)

"As a result of Medicare DRG payment to hospitals in the area you serve, has your agency experienced any of the following: d) Changes in your ability to refer clients to hospitals?"
*Data are for the 1984–86 time period.
**Data are for the 1986–87 time period.

Discussion

Study data suggest that the community-based service system is becoming saturated with physically sicker, heavier-care clients filtering down through the post-hospital community care services, affecting the service packages of both medical and social service agencies. There are three potential implications for the clients of these provider agencies:

- If the situation continues to move in the direction begun with PPS, there is likely to be a trade-off between our society's ability to meet the needs of the post-acute elderly as opposed to needs of the chronically ill elderly who have not been recently hospitalized. This could create problems of access for the chronically ill elderly residing in the community.
- Medicare coverage for services outside of the acute care setting is extremely limited. An increased need for these services can be expected to increase the already high out-of-pocket health care expenses of the elderly, creating problems of access for older persons with limited financial capacity.
- In other sections of our survey not dealing with DRGs specifically, we found that agencies were depending more on family caregivers. Increasing attention is being given to informal caregiving as a means to control costs. Insofar as possible, we expect that the informal care sector represents the "third generation" of DRG effects, as responsibility for care of the disabled and chronically ill older adults continues to shift to the informal sector.

We have examined some of the short-term effects of DRGs on a number of community agencies but we do not know how long-term these effects may be nor can we generalize our findings beyond the agencies and SMSAs studied. Continuing and more detailed research on the services and clients of providers is needed to determine if beneficiary access to both post-acute care and chronic care is adequate and whether the shifts of the type we describe are occurring more generally. Our findings also need to be further validated and complemented by research on the case-mix and service-mix of organizations of the type studied here. Given the probability method of sampling and the high response rates within the sample SMSAs, however, we are confident in, and disturbed by, our results.

American Cancer Society Research Grants in Primary Prevention and Detection

The American Cancer Society is expanding its research program in psychosocial and behavioral aspects of cancer to include primary prevention and detection. Investigators are encouraged to submit research and clinical grant proposals, and requests for support of personnel in research (Postdoctoral Fellowships, Physician's Research Training Fellowships, Junior Faculty Research Awards, Faculty Research Awards, and Scholar Awards) in these areas.

Applications will be peer-reviewed by the Scientific Advisory Committee on Psychosocial and Behavioral Research in competition with other applications assigned to this committee. Funding will be based primarily on the scientific merit of the proposal and relevance of the project to the Society's mission. Applications should be designed to test a well-defined hypothesis using rigorous, state of the art methodology.

Deadlines for receipt of applications for Research and Clinical Investigation Grants are April 1 and November 1. For Grants in Support of Personnel for Research they are March 1 and October 1.

Brochures describing these programs are available upon request from: American Cancer Society, Inc., Research Department, 1599 Clifton Road, NE, Atlanta, GA 30329. Tel: 404/329-7558.

The Prevention of Intellectual Impairment in Children of Impoverished Families: Findings of a Randomized Trial of Educational Day Care

SANDRA L. MARTIN, PHD, CRAIG T. RAMEY, PHD, AND SHARON RAMEY, PHD

Abstract: We estimated the effects of an experimental educational day care program on the intellectual development of preschoolers from 86 high-risk families in a randomly allocated longitudinal study. At six through 54 months of age, the IQs of experimental program children ranged from 7.9 to 20.1 points higher than those of control children when maternal mental retardation and home environment effects were controlled; at every age, a greater proportion of the experimental program children had normal range IQs (> 84). In 13 children with retarded mothers, none of six experimental program children, but six of seven control children, had IQ scores below normal. (*Am J Public Health* 1990; 80:844–847.)

Introduction

Mild mental retardation is more prevalent among lower socioeconomic groups, unlike moderate, severe, and profound mental retardation which are fairly evenly distributed across socioeconomic groups.[1] Family and social problems of many low income families (e.g., low education, unemployment) have been associated with impaired intellectual functioning in general, and mild mental retardation in particular.[2,3] These findings, in combination with those of national surveys showing that 25 percent of the nation's preschool age children live in poverty,[4] suggest that mild mental retardation should be an important public health concern.

Preschool programs designed to enhance the intellectual development of high-risk children have generally been associated with positive outcomes; however, the intellectual gains associated with the programs are often of limited duration.[5]

The goal of this report is to evaluate simultaneously the effects of an educational day care program (i.e., the Carolina Abecedarian Project) and familial factors, specifically maternal retardation and home environment, on the intellectual development of high-risk children throughout their first four and a half years of life. Previous investigation of this sample found that educational day care led to improved intellectual functioning;[6*] however, the impact of multiple potentially confounding factors was not evaluated.

Methods

Intervention Procedures

The Carolina Abecedarian Project is a randomly allocated, controlled, longitudinal investigation of the effectiveness of educational day care in enhancing the intellectual ability of children from impoverished multi-problem families. Children assigned to the experimental condition entered day care between 6 and 12 weeks of age, and remained in care for five days a week, 50 weeks a year. The program was designed to promote social and cognitive growth in an orderly, friendly environment.[7,8]

Sample Selection

A total of 120 pregnant women whose unborn children (the target children) were at high-risk for intellectual impairment were identified by public health agencies and hospitals. High-risk status was defined by an index score composed of 14 risk factors for intellectual impairment.[9] Of the 120 families randomly assigned to either the experimental or control group, 107 continued participation for at least 54 months.[6] This report focuses on 86 (80 percent) of these 107 families for whom complete follow-up information is available (41 experimentals and 45 controls). No statistically significant differences were detected between the 86 families with complete information and the 21 families with incomplete information in terms of condition assignment, maternal IQ, or maternal education.

Table 1 shows the sociodemographic comparability of the experimental and control groups at study enrollment. Study families were primarily Black, low-income, single parent families. Mothers tended to be young and to have low IQs and low education levels. Target children were predominantly firstborns.

Assessment Instruments

The intellectual development of the children was evaluated using three standardized developmental and IQ tests.

TABLE 1—Characteristics of the Families at Study Enrollment

Characteristics	Control Group (n = 45)	Experimental Group (n = 41)
	n (%)	*n (%)*
Race		
Black	45 (100)	39 (95)
White	0 (0)	2 (5)

The Mental Development Index of the Bayley Scales of Infant Development[10] was used for assessments at 6, 12, and 18 months of age, the Stanford-Binet Intelligence Scale[11] for ages 24, 36, and 48 months, and the McCarthy Scales of Children's Ability[12] for ages 42 and 54 months.

For some analyses, children were classified into one of three groups on the basis of their IQ scores. Employing standard clinical cutpoints,[13,14] children with IQs of 70 or less were categorized within the mentally retarded range of intellectual ability, children with IQs between 71 and 84 fell within the borderline intellectual functioning range, and children who scored 85 or more fell within the normal range of intellectual ability; children could move across groups dependent upon their test scores at particular ages.

The Home Observation for Measurement of the Environment (HOME)[15] was employed to quantify the degree to which each child's home surroundings provided an age-appropriate, potentially stimulating environment. The 45-item infant version HOME was administered at 6, 18, and 30 months, and the 80-item child version at 42 and 54 months. The mean HOME scores of the experimental and control groups were comparable at each of the five assessments and evidenced little within-family variation over time.[16] Therefore, the five evaluations were summed to create a HOME-SUM score representative of each child's home environment throughout the follow-up. For purposes of analysis, the study homes were categorized into two groups: "more stimulating" homes (i.e., homes at or above this sample's mean HOME-SUM score), and "less stimulating" homes (i.e., homes below this sample's mean HOME-SUM score). Twenty-two (54 percent) of the experimental families were classified as having more stimulating homes, as were 19 (42 percent) of the control families.

Analyses

Descriptive statistics were calculated to compare the experimental and control children in terms of their mean IQ scores and the proportion of children who fell within the mentally retarded, borderline, and normal IQ ranges. A repeated measures multivariate analysis of variance procedure[17] was employed to evaluate the effects of the experimental day care on the IQ scores of the study children across time, while controlling for, and examining the impact of, familial factors. The children's IQs were modeled using the following predictor variables: experimental educational day care (yes or no); maternal mental retardation (yes or no); home environment (more or less stimulating); annual family income; maternal age; maternal education level; maternal marital status; and the number of siblings. Using a backward elimination modeling strategy,[18] the full model was reduced to a smaller final model containing educational day care, maternal retardation, and home environment. The Wilks Lambda criterion (with a type I error rate of .05) was used to evaluate all multivariate tests. Effect sizes were measured using estimated regression coefficients, and 95% confidence intervals were calculated.

Results

Table 2 shows that the mean IQ scores of the experimental program children were above the general population average of 100 at all but one assessment, unlike that of the controls. At all time points, a greater percentage of experimentals than controls fell within the normal range of intellectual ability. Furthermore, at all ages except 24 months, a greater percentage of controls fell within the mentally retarded range of intellectual ability. At 54 months, 93 percent of the experimentals vs 69 percent of the controls had IQs within the normal range.

The 13 children of mentally retarded mothers were examined in detail. At 6 and 12 months, the mean IQ scores of the six experimental program children of retarded mothers were comparable to those of the seven control children of retarded mothers, with all mean scores being slightly above 100. However, by the 54-month assessment, the mean IQ of the experimental program children of retarded mothers was 22 points higher than that of the control children of retarded mothers (95 vs 73). The IQ scores of six (86 percent) of the seven control children of retarded mothers fell below the normal IQ range at 54 months (three within the mentally retarded range and three within the borderline intellectual functioning range). However, the IQ scores of all of the six experimental program children of retarded mothers were within the normal IQ range at the final assessment.

The repeated measures multivariate analysis of the entire sample found that the experimental and control groups differed significantly in their overall level of IQ averaged over time when the effects of maternal retardation and home environment were controlled ($F_{(1,82)} = 49.12$, $p = .0001$), with the experimental group having a greater grand mean than the comparison group. The two groups also differed in their patterns of change in IQ across time ($F_{(7,76)} = 4.76$, $p = .0002$). Stepdown contrasts examining the differences in IQ between successive time periods found that the groups differed significantly on all comparisons except for those assessing change between the 6 and 12 month assessments and the 42 and 48 month assessments.

As shown in Table 3, positive educational day care effects were found at all ages, with the mean IQ of the experimental children averaging from 7.9 to 20.1 points

TABLE 2—Mean IQ, Standard Deviation, and the Number and Percentage of Children in the Mentally Retarded (IQ < 71), Borderline Intellectual Functioning (70 < IQ < 85), and Normal (IQ > 84) IQ Ranges at 6 through 54 Months of Age

TABLE 3—Estimated Regression Coefficients and Associated 95% Confidence Intervals

Age in months	Regression Coefficients (95% CI)		
	Educational Day Care	Maternal Retardation	Home Environment
6	8.2 (2.2,14.1)	1.7 (−6.9,10.3)	4.8 (−1.4,11.0)
12	7.9 (2.0,13.7)	1.0 (−7.4,9.4)	4.9 (−1.2,10.9)
18	20.1 (15.0,25.2)	−3.3 (−10.6,4.1)	6.6 (1.3,10.9)
24	12.7 (8.9,16.7)	−4.3 (−9.9,1.5)	5.1 (0.9,9.3)
36	18.6 (13.5,23.7)	−8.2 (−15.6,−0.8)	8.6 (3.2,13.9)
42	10.2 (5.8,14.7)	−12.2 (−18.6,−5.8)	5.3 (0.7,9.9)
48	13.2 (8.5,17.9)	−11.7 (−18.5,−4.9)	8.9 (4.0,13.8)
54	9.1 (4.5,13.8)	−11.8 (−18.5,−5.1)	7.9 (3.0,12.7)

Note that for the multivariate analysis: educational day care was coded as 1 if experimental, 0 if control; maternal retardation was coded as 1 if retarded (IQ < 71), 0 if not retarded (IQ > 70); and home environment was coded as 1 if more stimulating (HOME-SUM scores above the mean), 0 if less stimulating (HOME-SUM scores below the mean).

higher than that of the control children when the effects of maternal retardation and home environment were controlled. The estimated effects of maternal retardation vary with the age of the children, the coefficients being small and positive at 6 and 12 months, but negative and progressively larger from 18 months onward. By 54 months, children with retarded mothers had IQ scores which averaged 11.8 points lower than children with non-retarded mothers, when the effects of educational day care and home environment were controlled. The effects of a more stimulating home environment were positive at every time point and increased over time. By the final assessment, children with more stimulating homes had IQ scores which averaged 7.9 points higher than did the children with less stimulating homes, controlling for the effects of educational day care and maternal retardation.

Discussion

The findings suggest that educational day care, maternal intelligence, and home environment each contributes to the developmental course of children's intellectual abilities. However, some cautionary comments and explanations are in order.

First, since the IQ scores of the experimental program children were consistently greater than those of the controls, one may ask whether the intellectual advantage of the experimental group was the result of the educational day care or the initial allocation procedure (i.e., were the children most at risk for intellectual impairment disproportionately allocated to the control group?). The facts that random allocation procedures were employed to assign families to groups, that known risk factors were evenly distributed between the groups, and that the experimental children had been in day care for at least three months prior to the initial IQ assessment, argue for the IQ differences being attributable to the educational day care program. Furthermore, the initial similarity of the IQ scores of the experimental and control group children of retarded mothers (i.e., all scored within the normal IQ range at 6 and 12 months of age) and the later dissimilarity of their scores (i.e., only 14 percent of the controls were in the normal IQ range at 54 months of age, compared to all of the experimentals) supports the notion that the educational day care resulted in improved intellectual functioning.

Second, issues arise concerning the patterns of change in IQ seen in the experimental and control groups over time. The decline in IQ seen in both groups after 12 months of age may be the result of at least two factors. The norms for the 12-month Bayley may be outdated, resulting in over-estimation of the true abilities of some children.[19] If the assessments at 6 and 12 months are inflated estimates of the children's functioning, while the later assessments are more accurate estimates, one would expect to see the observed decline in both groups of children after the 12-month evaluation. The differential magnitude of the decline (i.e., the downturn in scores was greater for the controls than for the experimentals) may be because the 6- and 12-month assessments focused on motor behaviors, while the later assessments incorporate more verbal behaviors. Perhaps the deficits associated with an impoverished environment may be mostly cognitive and verbal, rather than motor. This also could explain why the greatest fall in mean IQ after the 12-month assessment occurred in the subgroup of control children of mentally retarded mothers.

Improvement in the control group's mean IQ after 36 months of age may be due to the beneficial impact of community day care programs since approximately half of the control families entered their children into licensed community day care programs when the children were around three years old. A recent study of the impact of community day care in this sample of children concluded that the controls benefited intellectually from the community day care experience, although not to the same degree as the experimentals benefited from the Abecedarian educational day care.[20]

The positive impact of educational day care was especially pronounced for the children with mentally retarded mothers. At 6 months of age, all experimental and control children of retarded mothers had IQ scores within the normal range; however, by 54 months, all experimental group children of retarded mothers, but only 14 percent of the control children of retarded mothers, had normal range IQ scores. Although the number of children with retarded mothers in this sample is small (n = 13), the strong beneficial impact of this intervention merits attention because these children are at extreme risk for intellectual impairment.[21,22]

Given the beneficial effect of early educational day care in this sample of children with retarded mothers, the question arises as to whether families such as these typically receive day care services for their children. Data from the US National Longitudinal Survey of Youth[23] suggest that this is not the case: only 6 percent of the lowest functioning mothers of preschoolers (i.e., those mothers who scored in the bottom 5 percent on a standardized achievement test) enrolled their children in day care, compared to 20 percent of the highest functioning mothers (i.e., those mothers who scored in the top 95 percent on the achievement test). Thus the children who may be in most need of educational day care do not tend to receive these services. Given the positive findings of the Carolina Abecedarian Project, the children of low functioning mothers appear to be a group which public health policies should target to receive high quality educational day care interventions.

In addition to the educational day care effect, this study found both maternal mental retardation and home environment to be independent predictors of children's IQ scores. By the final 54-month assessment, the IQ scores of the children of retarded mothers averaged 12 points less than those of the children of non-retarded mothers, and the IQ scores of the children from more stimulating homes averaged 8 points higher than those of the children from less stimulating homes, when the effect of the experimental day care was controlled.

Finally, one may ask whether educational day care programs for impoverished families are cost-effective. Although, to date, no specific cost-benefit analyses have been performed using the Abecedarian data, a study of the teenage mothers in the sample found that by the 54-month evaluation, mothers in the experimental group were significantly more likely to have graduated from high school and be self-supporting than were mothers in the control group.[24] Given the large numbers of teenage mothers and children living in poverty in the United States today, the provision of high quality educational day care services to impoverished families may be a feasible strategy aimed at the prevention of mild mental retardation.

Yom Kippur Services Open to APHA Convention Attendees

Individuals planning to attend pre-convention activities related to the American Public Health Association's annual meeting this fall in New York City should note that Yom Kippur falls on Saturday, September 29. For those pre-annual meeting participants who wish to attend Yom Kippur services, two New York City educational institutions offer services open to the public.

- Jewish Theological Seminary of America
  3080 Broadway, NYC
  Tel: 212/678-8000
  (Two separate services are conducted: sex-segregated and open.)
- Columbia University
  116th Street and Broadway, NYC
  212/280-1754
  (Student-led services.)

Risk Factors for Syphilis: Cocaine Use and Prostitution

ROBERT T. ROLFS, MD, MARTIN GOLDBERG, AND ROBERT G. SHARRAR, MD, MSc

Abstract: In Philadelphia, a large increase in syphilis among minority group heterosexuals began in 1986 and preceded similar increases elsewhere in the United States. To determine reasons for this increase, we conducted a case-control study in the metropolitan sexually transmitted diseases clinic during 1987 and 1988. Cocaine use (odds ratio [OR] 3.1; 95% confidence interval [95% CI] = 1.5, 6.5 among men; OR 5.8; 95% CI = 1.5, 33 among women) and exchange of drugs for sex (OR 3.5; 95% CI = 1.4, 8.7 among men) were risk factors for syphilis. Although cocaine users reported more sexual partners and more frequently reported sex with prostitutes, cocaine use remained a risk factor after adjustment for these behaviors. These data suggest that sexual behavior or another factor, such as availability or utilization of health care, among cocaine users leads to increased risk of syphilis in this population. Increases in cocaine use may be partly responsible for recent increases in syphilis incidence in the United States. (*Am J Public Health* 1990; 80:853–857.)

Introduction

In 1986, the incidence of reported primary and secondary syphilis in Philadelphia, Pennsylvania was 38.0 cases per 100,000 persons, a 62 percent increase compared to 1985. This increase reversed a four-year period of declining syphilis incidence in Philadelphia. The increase continued during 1987 and 1988, reaching 71.9 cases/100,000 in 1988. This increase preceded increases in other areas, such as New York City, California, and Florida.[1] In Philadelphia, as in the rest of the United States, increases were greatest for Black and Hispanic heterosexuals.[2]

Reports by syphilis interviewers, and a review of interview records between 1985 and 1987,[3] suggested that an increasing proportion of syphilis patients were users of illegal drugs, especially of smoked or "crack" cocaine. In addition, use of smoked cocaine increased during this period in Philadelphia and in many other metropolitan areas experiencing increases in syphilis.[4,5] Authorities suggested that cocaine-addicted female prostitutes, exchanging sex for a dose of "crack" cocaine, were responsible for syphilis outbreaks in Philadelphia and elsewhere. To test this hypothesis and to explore the relation between cocaine use and syphilis, we conducted a prospective case-control study of risk factors for syphilis in the sexually transmitted disease (STD) clinic operated by the city of Philadelphia.

Methods

Subjects

Consecutive patients diagnosed with primary and secondary syphilis and latent syphilis of less than six months duration and interviewed for partner notification at the STD clinic were enrolled as cases. Interviews occurred between September 1987 and January 1988. We accepted a clinical diagnosis of syphilis if confirmed by review of test results by the syphilis interviewers. During the study period, 82 percent of reported syphilis cases were interviewed for partner notification. We excluded patients whose partner notification interview occurred outside of the STD clinic (approximately 30 percent of interviews) because information obtained in these settings might not be comparable to that obtained in the STD clinic.

Controls were recruited from among other patients seen in the STD clinic during the same time period. We enrolled as controls consecutive patients seen in the clinic during specified periods of the day and week who had not had syphilis during the past six months. Since anecdotal evidence suggested that gonorrhea was also linked to cocaine use, we also excluded patients with gonorrhea from the control group. All male controls with symptoms or signs of urethritis and all female controls had negative cultures for gonorrhea. All patients were tested serologically for syphilis.

Measurements

A standard questionnaire administered to all patients by STD interviewers recorded demographic data, STD history, reason for coming to the clinic, site at which medical care was initially sought, medical diagnoses and laboratory test results from that clinic visit, as well as specific questions about sexual and drug use behavior during the three-month period before the clinic visit. This time interval was chosen to be short enough for accurate recall but long enough to reflect behavior during the period immediately before infection for most patients. The questionnaire was administered before the usual partner notification interview for syphilis patients.

We abstracted results of partner notification efforts conducted on syphilis patients, after completion of the study. We recorded the number of exposed sexual partners identified and the outcome of partner notification efforts for each identified partner. The abstracter was blinded to the patients' questionnaire results.

Analysis

We calculated crude and adjusted odds ratios and 95% confidence intervals using standard methods.[6,7] We used chi-square analysis or Fisher's exact test to compare categorical variables and Student's t test and the Wilcoxon rank-sum test to compare continuous variables.

We used the Statistical Analysis System logistic regression package[8] for multivariate analyses. Separate logistic regression models were used for men and women to adjust for confounding variables. Variables examined in these analyses included: age, race, education, histories of syphilis and gonorrhea, reason for coming to clinic, location of residence

within the city, and numbers of sexual partners in the last three months and last five years.

Results

We initially enrolled 170 syphilis patients (cases) and 166 controls in the study. Twenty percent of cases had primary syphilis, 36 percent had secondary syphilis, and 44 percent had latent syphilis. Sixty-nine percent of controls received a diagnosis associated with *Chlamydia trachomatis* (non-gonococcal urethritis, mucopurulent cervicitis, pelvic inflammatory disease), 10 percent were diagnosed with trichomoniasis, 5 percent with pubic lice, 5 percent with genital warts, 2 percent with genital herpes, and 1 percent with chancroid. Fourteen patients (9 percent) received more than one STD diagnosis. In 16 percent of control patients, no sexually transmitted infection was detected.

Nineteen percent of male cases reported sex with another man compared with 7 percent of controls. All men reporting sex with another man were excluded from the rest of these analyses, since the goal of this study was to determine reasons for the increase in syphilis among heterosexuals.

Among heterosexuals, cases were more likely than controls to be women and of Hispanic origin, and had completed fewer years of school (Table 1). The number of sexual partners reported in the last three months and the last five years were not significantly different between cases and controls. Controls were more likely to have come voluntarily to the clinic for care while over half of cases were detected by serologic screening or health department partner notification efforts. Controls were significantly more likely to have a past history of gonorrhea but history of syphilis was not different.

Use of cocaine during the three months before the interview was significantly more common among both male and female cases (Tables 2 and 3). Among men, having given a woman drugs in exchange for sex, having had sex with a woman met at a "crack house" or a place where drugs are sold or used ("crack house" sex), and sex with a woman on the same day she was met (first day sex) were also risk factors for syphilis. Twenty-six of 27 men, for whom the specific drug exchanged for sex was recorded, reported trading cocaine for sex. These associations persisted after adjustment for age, race, education, location of residence within the city, and whether the patient presented voluntarily to the city STD clinic for care, using logistic regression (Table 2). Adjustment for the number of sexual partners reported in the last three months and five years also did not change the risk estimates.

Among women, having accepted money or drugs for sex (prostitution) was more common among cases than controls (Table 3). "Crack house" sex and first day sex were uncommon among women and were not associated with syphilis. We could not obtain valid adjusted odds ratio estimates for women using logistic regression, because of the small number of female subjects. Odds ratio estimates were not reduced in any case, however.

When we examined route of cocaine use, the patterns of association were somewhat different for men and women, although the small number of women limits these comparisons. Among men, the strongest association was with intravenous cocaine use, although non-intravenous use was more commonly reported and was also a significant risk factor for syphilis. In contrast to men, non-intravenous cocaine use, primarily by the nasal route, was the strongest risk factor for syphilis among women. In this population, nearly all intravenous drug users reported using intravenous cocaine.

TABLE 1—Characteristics of Heterosexual Patients in Study, Philadelphia 1987–88

Characteristics	Cases (n = 147)	Controls (n = 157)	P value

TABLE 2—Risk Factors for Syphilis among Heterosexual Men in Philadelphia, 1987–88

Risk Behavior[a]	Cases (n = 95)		Controls (n = 126)		Odds Ratio (95% CI)	
	n	(%)	n	(%)	Crude	Adjusted[b]
No cocaine use	50	(53)	93	(74)	1.0	
Cocaine use	45	(47)	33	(26)	2.5 (1.4,4.5)	3.1 (1.5,6.5)
Cocaine, by route of use[c]						
Intravenous	10	(11)	1	(1)	18.6 (2.3, 150)	24.1 (2.0, 295)
Smoked	15	(16)	13	(10)	2.2 (0.9,5.3)	2.2 (0.8,6.3)
Nasal and unknown	20	(21)	19	(15)	2.0 (0.9,4.3)	2.7 (1.1,6.9)
Cocaine use, other than intravenous	35	(37)	32	(25)	2.0 (1.1,3.8)	2.5 (1.2,5.4)
Sex with prostitute	26	(27)	22	(17)	1.8 (0.9,4.7)	2.4 (1.1,5.4)
Sex with prostitute by what was exchanged[d]						
Drugs	21	(22)	14	(11)	2.3 (1.1,4.7)	3.5 (1.4,8.7)
Money	15	(16)	11	(9)	2.1 (0.9,4.7)	2.9 (1.03,8.5)
"Crack house" sex[e]	23	(25)	16	(13)	2.2 (1.1,4.5)	2.6 (1.1,6.2)
First day sex[f]	51	(54)	50	(40)	1.8 (1.03,3.0)	2.2 (1.1,4.4)

a) All behaviors refer to the 3 months prior to the interview.
b) Adjusted for age, race, education, geographic residence within the city, and whether patient presented voluntarily to STD clinic for care.
c) Route of cocaine use is classified hierarchically as follows: any intravenous, smoked but not intravenous, and nasal or unspecified route, but not intravenous or smoked.
d) Exchange of drugs and money are not mutually exclusive categories.
e) Sex with a woman met at a "crack house" or a place where drugs are sold or used.
f) Sex with a woman on the same day that woman was met.

TABLE 3—Risk Factors for Syphilis among Women in Philadelphia, 1987–88

Risk Behavior[a]	Cases (n = 52)		Controls (n = 31)		Odds Ratio (95% CI)
	n	(%)	n	(%)	
No cocaine use	33	(63)	28	(90)	1.0
Cocaine use	19	(37)	3	(10)	5.4 (1.4, 31)
Prostitution:	6	(12)	1	(3)	3.9 (0.4, 91)
"Crack house" sex[b]	2	(4)	3	(10)	0.4 (0.1,2.4)
First day sex[c]	8	(16)	6	(19)	0.8 (0.2,2.5)

a) All behaviors refer to the 3 months prior to the interview.
b) Sex with a man met at a "crack house" or a place where drugs are sold or used.
c) Sex with a man on the same day that man was met.

Cocaine use remained a significant risk factor after adjusting for sex with a prostitute among men (OR 2.4; 95% CI = 1.3, 4.4) and for prostitution among women (OR 4.6; 95% CI = 1.2, 31). Among men, "crack house" sex and having had sex with a prostitute appear to measure a common risk behavior. A large proportion of patients reporting "crack house" sex also reported having had sex with a prostitute, and no risk was attached to either risk factor when present alone, while risk was greatly increased when both behaviors were reported (OR, 6.2; 95% CI = 2.0, 19). Cocaine use remained a risk factor for syphilis after adjusting for "crack house" sex.

Cocaine users were more likely to report sex with a prostitute and other behaviors likely to increase syphilis transmission, such as greater number of sexual partners and first day sex (Table 4). Men who smoked cocaine reported the highest frequency of each of these behaviors. Women who used cocaine also reported more sexual partners in the last three months (mean, 3.7 compared to 1.2; $p < 0.01$) and were more likely to report prostitution (6/22 compared to 1/60; $p < 0.1$) than women who did not use cocaine.

Men with syphilis who reported IV drug use were significantly more likely to have been diagnosed with secondary syphilis (73 percent) than were men who did not report IV drug use (27 percent), and were somewhat less likely to have been diagnosed with primary syphilis (18 percent compared to 33 percent).

TABLE 4—Sexual Behavior Associated with Cocaine Use, Heterosexual Men, Philadelphia, 1987–88

Sexual Behavior[a]	Cocaine Use		No Cocaine Use		P value[b]
	n = 78	(%)	n = 143	(%)	
Exchanged money or drugs for sex	30	(38)	18	(13)	$p < .001$
Drugs for sex	28	(36)	7	(5)	$p < .001$
Sexual partners in last 3 months					
0–1	17	(22)	49	(35)	$p < .01$
2–3	33	(42)	69	(49)	
4–5	15	(19)	15	(11)	
6–10	8	(10)	4	(3)	
> 10	5	(6)	4	(3)	
First day sex	48	(62)	53	(37)	$p < .001$
"Crack house" sex	25	(32)	14	(10)	$p < .001$

a) All behaviors refer to the 3 month interval prior to interview.
b) All p values are by chi-square. Number of sexual partners in last 3 months yields a Wilcoxon rank-sum test p value < 0.001.

Partner notification results were available for 88 percent (130/147) of syphilis patients. While men who had sex with a prostitute and men who used cocaine reported significantly more sexual partners in the last three months than did men who reported neither risk behavior (means 4.3, 4.0, and 1.8, respectively; $p < 0.05$), the average number of exposed sexual partners identified for partner notification purposes was lower for men reporting sex with a prostitute and cocaine use than for men reporting neither behavior (0.7, 1.0, and 1.3, respectively; $p < 0.05$ for sex with a prostitute). Prostitution and cocaine use were not associated with partner notification effectiveness among women, but the number of women in each group was small.

Discussion

These data support the hypothesis that cocaine use and sexual behaviors related to it are risk factors for syphilis in Philadelphia. The association between syphilis and cocaine

use was not fully explained by contact with prostitutes among men or by prostitution among women.

This study has several potential limitations. Data were collected in a public STD clinic in Philadelphia; results may not be generalizable to other locations or other health care settings. Moreover, our control group was chosen to control for factors related to the tendency to seek care at a public STD clinic. If cocaine use is also important in the transmission of other sexually transmitted infections, associations between syphilis and cocaine use would be underestimated. We excluded gonorrhea patients from the control group because of the possible link between gonorrhea and cocaine use; gonorrhea incidence was increasing in Philadelphia when the study began. The information we collected on gonorrhea patients suggests our concern was valid. Gonorrhea patients reported cocaine use and sex with prostitutes nearly as frequently as did syphilis patients. In contrast, no consistent differences in the frequencies of these behaviors existed among controls with different diagnoses. The exclusion of patients with gonorrhea is further supported by a report linking illicit drug use with spread of penicillinase-producing *Neisseria gonorrhoeae* in King County, Washington.[9]

Selection bias[10] could occur if, among persons with sexually acquired infection, cocaine users are more or less likely than nonusers to be seen for care in the STD clinic. If cocaine users are less likely to seek care, active syphilis case detection (laboratory screening and partner notification) could artificially increase the proportion of syphilis patients who are cocaine users, producing a spurious association between syphilis and cocaine use. Patients who presented voluntarily to the clinic were as likely to report cocaine use and prostitution as were patients detected by health department partner notification efforts and screening, so this bias was probably absent.

High-risk sexual behaviors, such as sex with prostitutes, were common among cocaine users and are partly responsible for the increased risk of syphilis associated with cocaine use. However, cocaine use remained a risk factor after adjusting for differences in these sexual behaviors and is not merely a marker for differences in sexual behavior. Cocaine use may indicate a population with a greater prevalence of syphilis, resulting in increased risk of infection for any given behavior. An increased prevalence of syphilis among cocaine users could result from differences in sexual behavior, such as those described here. Alternatively, drug use may reduce health care access or utilization, resulting in longer duration of infectivity and therefore increased transmission.

While smoked cocaine or "crack" has received attention as a possible cause of increases in syphilis incidence,[11] cocaine use by all routes was associated with syphilis in this population. Especially among men, intravenous cocaine was most strongly associated with syphilis. "Crack" use, which has increased dramatically in the populations most affected by syphilis and was most strongly associated with high risk sexual behaviors among drug users in this population, may be a more important factor in the current syphilis epidemic. However, the strong association with intravenous cocaine use, not explained by differences in sexual behavior among drug users in this study, may suggest the importance of some other factor, such as health care behavior.

The strong association with intravenous drug use could also be due to nonsexual transmission due to needle sharing. *Treponema pallidum* has been transmitted by blood transfusion and by needle injury during surgery.[12,13] Patients with transfusion-acquired syphilis are usually diagnosed during the secondary stage,[12] since without cutaneous inoculation no primary lesion occurs. Intravenous drug users in this study were somewhat less likely to be diagnosed during the primary stage of syphilis. Further studies are warranted to determine if *T. pallidum* is transmitted by needle sharing.

Finding a history of gonorrhea more commonly reported by controls than by cases was unexpected. While gonorrhea incidence increased over this time period in Philadelphia, it decreased in the face of dramatic syphilis increases elsewhere in the United States. Cocaine-related behaviors which increased syphilis transmission would be expected to increase gonorrhea spread as well. Syphilis and gonorrhea may be distributed differently within the population,[14] providing one explanation for these otherwise surprising findings. Further study of differences between risk factors for syphilis and gonorrhea and of reasons for the divergence between trends in syphilis and gonorrhea incidence are needed.

Prostitution has increased syphilis transmission in the past,[15,16] although it has been overshadowed during the past two decades,[17,18] by the important role of homosexual and bisexual men in syphilis transmission during this time period.[19] Prostitution has also been linked to illegal drug use in the past,[20] often serving as a means of financing drug use. Our data suggest that trading sex for drugs, rather than for money, is an important risk factor for syphilis. However, an increased number of prostitutes and persons exposed to prostitutes, due to the greater availability and use of cocaine, is probably more important than whether drugs or money are exchanged.

Our results are consistent with data from Oregon which suggest that partner notification is less effective among persons trading sex for drugs.[21] Other tools of disease control, such as targeted screening and presumptive treatment,[22] may be useful in appropriately defined populations and settings. Since delay in seeking or gaining access to medical treatment may be important, barriers which prevent drug users from obtaining medical care should be removed.

HIV infection is more prevalent among heterosexual Blacks and Hispanics in inner cities than among heterosexuals in other settings, because of intravenous drug use-related transmission.[23] In addition to being important in needle use-related transmission,[24] cocaine use may also lead to increased sexual transmission of HIV. Because accumulating evidence suggests that genital ulceration is an important co-factor in HIV transmission,[25–27] the potential for sexual transmission within these settings is sizable.

ACKNOWLEDGMENTS

The authors wish to thank E. Russell Alexander, MD, and Stuart M. Berman, MD, for advice and critical review of the manuscript, Susan Bradley for data entry, Akbar Zaidi, PhD, for statistical assistance, the clinicians in the STD clinic who assisted in enrolling patients, and especially the disease intervention specialists in the Philadelphia Department of Public Health, STD Control Program, who conducted the interviews. The findings were presented to the Society for Epidemiologic Research, Vancouver, BC, Canada, June 14–17, 1988.

Workers Satisfied with Health Benefits, but Won't Pay More

Eighty-five percent of American workers are satisfied with their health care benefits, but they resist the idea of paying more for them or accepting less coverage, according to a poll by Northwestern National Life (NWNL) Insurance Company of Minneapolis. The survey involved interviews with 606 full-time employees whose health benefits are provided by private industry and state and local government.

Satisfaction with their benefits persisted whether they pay all, a portion, or none of the premium. However, many said they would contribute little, if anything, more to maintain current benefits: 39 percent said they would not pay even a dollar more; an additional 32 percent said they would agree to a monthly increase of less than $25.

A previous survey of 400 companies by NWNL last year had revealed that nine of 10 employers would soon ask workers to pay a much larger share of health care costs: 70 percent of employees felt the amount their employer now pays toward their health insurance is "about right." According to A. Foster Higgins and Company, employers contribute an average of $149 a month for each employee and his/her dependents for medical, dental, prescription drugs, and vision/hearing benefits.

Employees surveyed by NWNL this year indicated they view health benefits as an entitlement, and tend to be more satisfied with their plan when they have a choice of coverages and an understanding of their benefits. However, many employees are not aware of basic benefits information: 43 percent did not know the amount their employer pays as a premium; 53 percent did not know if their health plan covers catastrophic illness or injury which could run as high as $400,000 (most health plans do cover their expenses, the report noted). Asked about changes they would like, nearly one-third said they would like costs to be reduced; 25 percent would like broader coverage for routine doctor visits, dental care and prescriptions; 9 percent wanted more freedom to choose doctors and hospitals; some wanted fewer restrictions, such as the requirement for pre-authorized care. But 21 percent said they would not change anything.

The results of the report are in: Employee Satisfaction with Health Benefits, (conducted by Winona Market Research Bureau) NWNL, PO Box 20, Minneapolis, MN 55440. Tel: 612/342-7137.

The Increasing Frequency of Heterosexually Acquired AIDS in the United States, 1983–88

KING K. HOLMES, MD, PHD, JOHN M. KARON, PHD, AND JOAN KREISS, MD, MSPH

Abstract: Of 88,510 cases of acquired immunodeficiency syndrome (AIDS) reported in adults in the United States from 1983 through 1988, the percentage attributed to reported heterosexual contact with persons known to be infected or at increased risk of infection with human immunodeficiency virus (HIV) has increased steadily from 0.9 percent in the first quarter of 1983 to 4.0 percent in the fourth quarter of 1988, from 0.1 (in 1983) to 1.4 percent (in 1988) among men, and from 13 (in 1983) to 28 percent (in 1988) among women. Among women, the cumulative incidence of AIDS attributable to heterosexual contact per million population is over 11 times greater for Blacks and Hispanics than for Whites. Among men, this incidence is over 10 times greater for Blacks and four times greater for Hispanics than for Whites. The pattern of distribution of heterosexually acquired AIDS parallels the distribution of other heterosexually transmitted diseases, which are also more frequent in Black and Hispanic inner-city populations. Drug use, exchange of sex for drugs or money, and early onset of sexual activity in adolescents are increasingly associated with heterosexually transmitted infections and are likely to be very important in heterosexual transmission of HIV in inner-city US populations. (*Am J Public Health* 1990; 80:858–862.)

Introduction

Early during the AIDS (acquired immunodeficiency syndrome) epidemic, there was considerable concern that AIDS would spread rapidly among heterosexuals in North America and Europe. These concerns were heightened by emerging evidence of heterosexual acquisition of AIDS in Africa. When the heterosexual AIDS epidemic did not rapidly materialize in industrialized countries, these concerns came to be regarded with skepticism. This paper provides an analysis of trends in the frequency and percentage of cases of AIDS in the United States thought to have been acquired heterosexually, together with a perspective on heterosexual transmission of HIV (human immunodeficiency virus) in the context of a general overview of heterosexually transmitted infections.

Methods

This report is based on the 88,510 adult (age at diagnosis at least 13 years) AIDS cases diagnosed in the United States between January 1, 1983 and December 31, 1988, and reported to the Centers for Disease Control (CDC) through June 30, 1989. AIDS case reporting is required in all states and territories, with individual city, state, and territorial health departments having the responsibility for surveillance. Each known case meeting a surveillance definition[1] is reported to CDC by the health department, with a likely mode of transmission based on a hierarchical definition (Appendix). If no risk factor for HIV infection is reported with the diagnosis, the health department contacts health care personnel and, if necessary, interviews the patient to obtain information concerning personal behavior, sexual contacts, and occupation that could result in exposure to HIV. A case is classified as "no identified risk" if the patient has died, is lost to follow-up, refused to be interviewed, could not be assigned to a risk group from the information obtained, or if information is still being sought.

From the University of Washington, Departments of Medicine and Epidemiology (Holmes, Kreiss); and the Division of HIV/AIDS, Center for Infectious Diseases, Centers for Disease Control, Atlanta (Karon). Address correspondence to King K. Holmes, MD, PhD, Director, Center for AIDS and STD, Department of Medicine ZA-92, Harborview Medical Center, 325 9th Avenue, Seattle, WA 98104. This paper, submitted to the Journal August 22, 1989, was revised and accepted for publication December 13, 1989.

In this report, we separate heterosexual transmission cases into two groups, corresponding to different epidemiologic characteristics and different trends over time. One group consists of cases classified as likely due to heterosexual transmission only because they were born in certain African or Caribbean countries where heterosexual contact is believed to play a major role in the transmission of HIV; these countries are designated by the World Health Organization as "Pattern II."[2] We concentrate on analyzing the remaining 2,637 heterosexual transmission cases that we designate as "reported heterosexual contact" cases. Of these 2,637 cases, 33 (1 percent) were born in these African or Caribbean countries but report heterosexual contact with intravenous drug users (IVDUs) (27 men, five women) or bisexual men (one woman).

We consider only cases of AIDS diagnosed after 1982 because the first reports of apparent heterosexual transmission were in late 1982.[3] Of the 1,394 adult cases of AIDS diagnosed before 1983, and not considered further here, two of the 1,305 men and 12 of the 89 women are classified as cases with reported heterosexual contact, and an additional 67 men and 10 women are classified as heterosexual cases due to birth in a "Pattern II" country.

Results

Trends in Heterosexually Acquired AIDS in US

The percentage of cases classified as due to reported heterosexual contact (as defined in Methods) increased from approximately 1 percent in 1983 to over 4 percent by the second quarter of 1988, while the percentage of cases classified as "heterosexual" cases in patients from "Pattern II" countries declined from over 4 percent in the first half of 1983 to about 1 percent by the end of 1988 (Figure 1). Only by separating these two groups can the increasing importance of known heterosexual contact cases be appreciated.[4] When these groups are not separated, no temporal trend in the percentage of AIDS cases due to heterosexual transmission is found.[5]

Table 1 shows the number and percentage of adult US cases of AIDS attributed to reported heterosexual contact for men and women by year of diagnosis (1983–88). The increase in annual percentages is especially striking for men (within each race/ethnicity group) and for non-Hispanic White women, but in no group was this increase steady over time.

TABLE 1—Number and Percent[a] of Adult AIDS Cases in the United States Attributed to Reported Heterosexual Contact,[b] by Gender and Race or Ethnicity, Diagnosed during 1983–88.

Year of Diagnosis	Non-Hispanic White N (%)	Hispanic N (%)	Black N (%)	All[c] N (%)
Men				
1983	0 (0.0)	0 (0.0)	2 (0.3)	2 (0.1)
1984	6 (0.2)	1 (0.1)	12 (1.0)	19 (0.4)
1985	9 (0.1)	2 (0.1)	21 (0.9)	32 (0.3)
1986	22 (0.2)	11 (0.5)	42 (1.2)	75 (0.5)
1987	77 (0.6)	28 (0.9)	105 (2.0)	212 (0.9)
1988[d]	116 (0.8)	49 (1.2)	161 (2.6)	328 (1.4)
All	230 (0.5)	91 (0.8)	343 (1.8)	668 (0.8)
Women				
1983	5 (10)	8 (18)	12 (13)	25 (13)
1984	12 (13)	21 (27)	31 (16)	64 (18)
1985	43 (21)	52 (34)	84 (22)	179 (24)
1986	100 (26)	85 (34)	158 (23)	347 (26)
1987	164 (25)	141 (34)	264 (23)	573 (25)
1988[d]	216 (29)	210 (37)	342 (23)	781 (28)
All	540 (25)	517 (34)	891 (22)	1969 (25)

[a]Of all adult cases with the same race/ethnicity and gender.
[b]Excludes cases in people without other identified risk factors who were born in "Pattern II" countries (see Appendix), where heterosexual transmission is believed to play a major role in HIV transmission.
[c]Includes cases in other races. In men, 2 of 486 cases in Asians, 1 of 87 in American Indians, and 1 of 187 in persons with race unknown are attributed to heterosexual contact. In women, the corresponding numbers are 13 of 44, 6 of 17, and 2 of 17.
[d]Reporting of cases is incomplete, especially for cases diagnosed in 1988.

Persons born in Puerto Rico have been overrepresented in Hispanic heterosexual AIDS cases. Of the cases in men, 39 (43 percent) were known to be born in Puerto Rico; of those in women, 157 (30 percent) were born in Puerto Rico. In contrast, in 1980 less than 7 percent of all US Hispanics had been born in Puerto Rico.[6]

Although the rate of increase in the percentage of cases attributed to reported heterosexual contact has been greatest for men, the absolute percentage of cases attributed to reported heterosexual contact is much greater for women. For cases of AIDS diagnosed during 1988, the overall percentage of cases attributed to reported heterosexual contact is 20 times higher for women than for men, and the actual number of cases also was higher for women from 1983 through 1988. The female to male ratio of the number of heterosexually acquired cases for 1988 was 1.9:1 for Whites, 2.1:1 for Blacks, and 4.3:1 for Hispanics.

Although the percentage of reported cases of AIDS attributed to reported heterosexual contact does not differ greatly by race or ethnicity, the cumulative incidence of such cases (1983–88) was much higher for Blacks and substantially higher for Hispanics than for Whites (Table 2). The cumulative incidence of such cases per million adults, 1983–88, was over 10 times higher for Black men and four times higher for Hispanic men than for White men. Among women, the incidence was more than 11 times higher for Blacks and Hispanics than for Whites. As discussed below, this is similar to what is currently seen for certain other sexually transmitted diseases.

The temporal pattern of the percentage of cases attributed to heterosexual acquisition by women may also be somewhat different from that seen in men. In each racial group, there was an appreciable percentage of heterosexual cases in women as early as 1982 (at least 6 percent in each group, data not shown). The percentage has increased most rapidly among White women, from 10 percent in 1983 to 29 percent during 1988.

TABLE 2—Cumulative Incidence[a] (1983–88) of AIDS Cases Attributed to Reported Heterosexual Contact, 1983–88, by Race, Ethnicity, and Gender

Race/Ethnicity	Men		Women	
	Cumulative Incidence	Ratio vs. whites	Cumulative Incidence	Ratio vs. whites
White	3.0	1.0	6.6	1.0
Black	32.6	10.7	73.6	11.1
Hispanic	13.2	4.4	74.1	11.2

[a]Per million persons, ages ≥13. The estimated population sizes, in thousands, for July 1988, were 81,563 for White women; 12,106 for Black women; 6,975 for Hispanic women; 75,868 for White men; 10,535 for Black men; and 6,869 for Hispanic men.

Source of Heterosexually Acquired AIDS

Table 3 summarizes the distribution of the sex partner's risk group for cases of AIDS attributed to reported heterosexual contact, by race and gender of the index person with HIV infection. IVDUs comprised a substantially lower percentage of the male sex partners for White than for Black or Hispanic women. Bisexual men comprised a much larger percentage of the male sex partners for White women with AIDS than for Black or Hispanic women with AIDS.

The racial distribution of female heterosexual AIDS cases stating that their contact was an IVDU (20 percent White, 31 percent Hispanic, 48 percent Black) was nearly identical to the corresponding racial distribution of male IVDU AIDS cases diagnosed during 1983–88 (19, 33, and 48 percent, respectively). Whites were overrepresented and

TABLE 3—Distribution of Partner's Risk Group for Reported Heterosexual Contact AIDS Cases,[a] by Race, Ethnicity, and Gender of Index AIDS Case, for Cases Diagnosed during 1983–88

Partner's Risk Group	Non-Hispanic White N (%)	Hispanic N (%)	Black N (%)	All[b] N (%)
Men				
Intravenous drug user	148 (64)	67 (74)	270 (79)	487 (73)
Pattern II[c]	17 (7)	3 (3)	17 (5)	37 (6)
Blood product transfusion	8 (3)	0 (0)	4 (1)	14 (2)
Other[d]	57 (25)	21 (23)	52 (15)	130 (19)
All	230 (100)	91 (100)	343 (100)	668 (100)
Women				
Intravenous drug user	273 (51)	439 (85)	679 (76)	1400 (71)
Bisexual	138 (26)	35 (7)	86 (10)	262 (13)

Blood product transfusion	37 (7)	5 (1)	3 (0)	46 (2)
Hemophiliac	27 (5)	1 (0)	2 (0)	31 (2)
Other[d]	65 (12)	37 (7)	97 (11)	206 (10)
All	540 (100)	517 (100)	891 (100)	1969 (100)

[a]Excludes cases in people without other identified risk factors who were born in Pattern II countries (see Appendix), where heterosexual transmission is believed to play the major role in HIV transmission.
[b]Includes 4 men and 21 women of other races (see Table 1).
[c]21 of 37 men and 23 of 24 women were Haitians; the remaining 17 cases were born in sub-Saharan Africa.
[d]101 men and 179 women with heterosexual partner with HIV infection or AIDS but risk group not specified; 17 men and 14 women with heterosexual partner with uncertain HIV status and no indicated risk group; and 3 men with infected female partners who received clotting factors.

Hispanics were somewhat underrepresented in the male heterosexual AIDS cases stating contact with an IVDU compared to the racial distribution of female IVDU AIDS cases diagnosed 1983–88; the distributions were 30 percent White, 14 percent Hispanic, and 55 percent Black for male heterosexual cases reporting contact with an IVDU vs 22, 20, and 58 percent, respectively, for female IVDU cases.

Bias in Attribution

A possible source of bias is denial of other risk factors, such as IVDU and homosexual contact, perhaps as a result of an increasing awareness of heterosexual transmission. We examined the diseases present at diagnosis (Appendix). Of the 13,927 AIDS cases diagnosed in men during 1981–88 which included a report of Kaposi's sarcoma (KS), 13,177 (95 percent) were in homosexual or bisexual men (including 1,217 who were also IVDU). If the increase in the proportion of male cases attributed to heterosexual contact was primarily due to denial of homosexual contact, we would expect the percentage of reported heterosexual contact cases who had KS to change during 1984–88 to resemble the corresponding percentage in homosexual transmission cases more than the percentages in IVDUs and transfusion recipients.

We examined the annual percentages of male AIDS cases with KS during 1984–88 in these risk groups (Table 4). The percentage of AIDS cases in homosexual or bisexual men with KS declined during this period from 34 to 14 percent. The percentage of male AIDS cases attributed to heterosexual contact in 1988 was more than three times that in 1984. If this increase was due only to misclassification of homosexual contact AIDS cases, then at least two-thirds of the male heterosexual contact cases diagnosed in 1988 actually were due to homosexual transmission, so we would expect a diagnosis of KS in at least two-thirds of 14 percent, or about 10 percent, of the male AIDS cases attributed to heterosexual contact diagnosed during 1988. In fact, the percentage of heterosexual contact AIDS cases with KS remained at 5 to 6 percent for cases diagnosed during 1984–87, and was less than 4 percent for cases diagnosed during 1988. Thus KS in men with AIDS attributed to heterosexual transmission resembles the pattern of KS in male IVDUs and male transfusion recipients with AIDS (Table 4) much more than the pattern of KS in male homosexual transmission AIDS cases.

Discussion

Table 1 and Figure 1 might actually understate somewhat the true proportion of AIDS cases resulting from heterosexual transmission in the United States. When AIDS cases initially reported with no identified risk were investigated (including patient reinterviews) by Castro, *et al*, approximately one-fifth were reclassified as attributable to heterosexual transmission.[7] Of cases that remained in this category after follow-up investigations were completed, 38 percent reported a history of sexually transmitted disease, and 34 percent of the men reported contact with female prostitutes. Over 4 percent of AIDS cases diagnosed in 1988 currently are classified in the no identifiable risk category. Thus, heterosexual transmission of HIV probably accounts for close to 5 percent of AIDS cases now being diagnosed in the United States. Furthermore, the hierarchical system of classifying cases may misclassify some heterosexually acquired cases among persons with multiple risk factors for HIV exposure into other risk groups. Extrapolation of present trends suggests that at least 7 percent of adult AIDS cases diagnosed in late 1990 will be classified as reported heterosexual transmission cases (J Karon, unpublished).

On the other hand, several possible sources of bias could inflate the percentages of cases attributed to reported heterosexual contact, particularly in men. One possible explanation is that the observed trend may be due to a decreasing percentage of cases in homosexual and bisexual men. However, even after excluding all AIDS cases attributed to sexual contact between men (with or without IVDU), the percentage of cases in men attributed to reported heterosexual contact increased from 1.6 percent of the cases diagnosed in 1984–85 to 4.7 percent of the cases diagnosed in 1988. Although male AIDS patients with KS might be questioned more carefully than male AIDS patients without KS about same sex contacts, the data in Table 4 are not consistent with the hypothesis that the increase in male AIDS cases attributed to reported heterosexual contact is due *primarily* to misclassification of homosexual or bisexual men with AIDS. Nevertheless, as heterosexual transmission of HIV has become more widely acknowledged recently, it may have become easier for persons with AIDS to claim heterosexual exposure instead of homosexual contact or IVDU. This might especially be a problem outside the original epicenters. Decreasing likelihood of investigation (because of rising case loads) and recruitment of less experienced interviewers could also

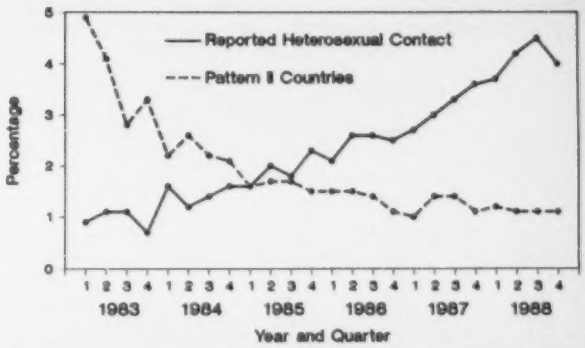

FIGURE 1—Trends in the Percentage of US Cases of AIDS Classified as Heterosexually Acquired, by Quarter of Diagnosis, 1983–88.
Declining trends in the percentage of cases born in WHO Pattern II countries (where heterosexual transmission predominates, such as Haiti and countries in sub-Saharan Africa) are offset by steadily increasing trends in the percentage of remaining US cases of AIDS attributed to reported heterosexual contact with an individual in another risk group for HIV infection or with someone known to have AIDS or HIV infection.

TABLE 4—Percentage of Men with AIDS with a Diagnosis of Kaposi's Sarcoma: Comparison of Reported Heterosexual Contact Cases, and Cases in Other Risk Groups, for Cases Diagnosed during 1984–88

Year of Diagnosis	Percent with Kaposi's Sarcoma			
	Homosexual or Bisexual[a]	Heterosexual IVDU	Transfusion Recipients	Reported Heterosexual Contact
1984	34.4	4.1	4.9	5.3
1985	28.4	2.9	5.7	6.2
1986	23.0	3.3	4.0	5.3
1987	18.1	2.4	3.6	5.7
1988	14.1	2.6	2.7	3.7

[a]Not also IVDU

account for some of the temporal increase in AIDS cases attributed to heterosexual contact.

Because the source of the HIV infection in most cases attributed to heterosexual contact is reported as an IVDU (Table 3), another indirect assessment of misclassification of these cases is a comparison of the geographic distributions of cases attributed to heterosexual contact and of those attributed to IVDU. The geographic distribution of heterosexual contact cases in women is similar to that of cases in male IVDUs, but there are substantial differences between these distributions for male heterosexual contact cases and female IVDU cases.[8] The ratio of male heterosexual contact cases to female IVDU cases is unusually low in New York and unusually high in Florida. Thus, the direction of any misclassification bias is uncertain. Geographic differences in follow-up of men claiming heterosexual contact as their only risk factor probably causes some of these geographic differences.

The change in the criteria for a reportable AIDS case in September 1987 may affect subsequent trends in the percent of cases attributed to reported heterosexual contact. The criteria were expanded to include both additional diseases and presumptive diagnoses of some opportunistic infections in persons known to be HIV-seropositive.[1] This change affected the percentages of cases in some risk groups, especially homosexual/bisexual men not using IV drugs (a sharp decrease) and heterosexual IVDU (a sharp increase).[9] These changes roughly offset each other in men, resulting in a modest increase in the proportion of cases attributed to reported heterosexual contact: for cases diagnosed during September 1987 through December 1988, this proportion is 1.2 percent (355 of 28,686 cases) diagnosed under the pre-1987 definition and 1.8 percent (199 of 10,894 cases) diagnosed under the expanded criteria. There is a marked effect in the opposite direction among women, with corresponding proportions 30 percent (840 of 2,756 cases diagnosed under the pre-1987 definition) and 22 percent (412 of 1,835 cases diagnosed under the expanded criteria), due to the increase in cases in women using IV drugs reported under the expanded criteria.

The present analysis shows that for AIDS cases reported from 1983 through 1988 and attributed to reported heterosexual contact, the cumulative incidence was much higher in Blacks and Hispanics than in Whites (Table 2). By comparison, for all cases of AIDS reported to CDC through January 18, 1988, Selik, *et al*, reported that the incidence was 2.8 times higher for Black men and 2.7 higher for Hispanic men than for White men; the incidence was 13.2 times higher for Black women and 8.1 times higher for Hispanic women than for White women.[10,11] Among Hispanics, incidence has been higher in those born in Puerto Rico than elsewhere, especially for IVDUs.[12] Thus, among men, the incidence of AIDS attributable to reported heterosexual contact for Blacks and Hispanics, relative to Whites, is higher than the overall risk of AIDS for Blacks and Hispanics, relative to Whites. The racial and ethnic differences in the incidence of AIDS attributed to reported heterosexual contact mirror the racial differences in incidence of AIDS associated with IVDU,[13] as well as differences in incidence of other sexually transmitted diseases (STD) as discussed below.

Further evidence for the importance of heterosexual acquisition of HIV among women comes from an analysis of the mother's exposure category for AIDS cases in children (age < 13 years at diagnosis). Of the 1,176 pediatric AIDS cases diagnosed through 1988 and reported to CDC through June 1989 that were attributable to perinatal transmission of HIV from a mother not born in a Pattern II country, 350 (30 percent) involved children born to mothers whose sex partners were in a risk group for HIV infection or had known HIV infection. Trends in this proportion should be further examined to see if the proportion is increasing over time.

Because of the delay of several years from acquisition of HIV until onset of AIDS, the increasing percentage of cases of AIDS seen now that are attributable to reported heterosexual contact actually reflects increasing trends in heterosexual transmission of HIV that were occurring several years ago. Data are not yet available concerning the current percentage of new HIV infections in the United States that are attributable to heterosexual acquisition, but there is a growing body of information about the prevalence of HIV in various nonrandom samples of populations that were not selected for specific high-risk behaviors.

For example, among US military applicants the overall prevalence of HIV seropositivity from October 1985 through March 1988 was 1.2 per 1,000, and was related to age, sex, race, and geographic area.[14,15] Male sex, Black race, and residence in a metropolitan area with a high incidence of AIDS were associated with the highest rates of HIV seropositivity. Seroprevalence rates exceeding 1 percent were observed in six counties in New York, New Jersey, California, and the District of Columbia. In future surveys, to assess further the role of heterosexual transmission in comparison with the role of other risk factors, it will be important to attempt representative sampling, and to conduct reinterviews of seropositive heterosexual persons.

So far, prostitution and sex with prostitutes have been implicated as important in the heterosexual transmission of HIV mainly in Pattern II countries.[2,16–19] Nonetheless, the history of prostitute contact among 34 percent of US male patients classified as having no identified risk[7] dictates that this issue be examined closely in the future. Other specific risk factors for heterosexual transmission include receptive anal intercourse for women[20] and immunosuppression in the source contact.[21] In Africa, genital ulcer disease[22–25] and lack of male circumcision[23,25] have been repeatedly implicated as cofactors associated with heterosexual transmission. Other sexually transmitted infections such as cervical chlamydial infection,[24] vaginal trichomoniasis,[26] and current oral contraceptive use[24] have been implicated as risk factors for heterosexual acquisition of HIV in single studies and require confirmation in other studies. Condom use has been associated with reduced risk of heterosexual transmission of HIV.[27–29]

Much remains to be learned about the epidemiology of heterosexually transmitted HIV infection in industrialized countries. However, the fact that HIV seropositivity among heterosexuals in the United States is associated with urban residence and certain racial minorities should not be automatically attributed solely to patterns of distribution of IVDU, since these associations also parallel the epidemiology of other heterosexually transmitted infections in North America. In the United States the reported incidence of other sexually transmitted diseases, such as gonorrhea, like the incidence of heterosexually acquired AIDS, is highest for persons of lowest socioeconomic status, higher for urban dwellers than for those living in the suburbs or rural areas, and much higher for Blacks and Hispanics than for Whites and Asians.[30] For example, during 1988 in the United States, the incidence of reported cases of gonorrhea was approximately 21 times higher in Black than in White women.[30]

Reporting of syphilis is considered to be more complete than reporting of gonorrhea. During 1987, the incidence rates of reported early syphilis in the United States were 25 times higher in Black men and 12 times higher in Hispanic men than in White men; the incidence was 31-fold higher in Black women and 8-fold higher in Hispanic women than in White women.[31] Chancroid, another sexually transmitted disease that has been increasing recently in incidence in the United States, has also occurred predominantly among Blacks and Hispanics, often in association with prostitution.[32]

It is evident that at least four phenomena in inner-city indigent populations could interact to promote heterosexual spread of HIV in the United States.[30] These include: 1) the pattern of sexual behavior, including early onset of sexual intercourse, prostitution, and sex with prostitutes; 2) epidemic spread in these populations of sexually transmitted diseases, including genital ulcer disease, which themselves may promote heterosexual spread of HIV; 3) transmission of HIV by IVDU; and 4) increasing use of drugs such as crack cocaine, which promotes high-risk sexual behavior, including traditional forms of prostitution and exchange of sex for drugs—a form of prostitution often involving teen-agers. Promotion of "safe sex" practices will be especially difficult in this group.

Culturally sensitive, age-specific social and health educational programs, endorsed by community leaders and beginning in early adolescence, if not sooner, are urgently needed to interrupt the heterosexual spread of HIV. These should be accompanied by programs to better control other STDs as risk factors for HIV transmission, and by programs to prevent and curtail illicit drug use.

APPENDIX

Risk Groups for AIDS/HIV Transmission

In the CDC hierarchical definition of risk group, a person with AIDS who reports sexual contact with a member of the same sex (if male), receipt of clotting factors, or IVDU will not be classified as having AIDS due to heterosexual transmission. In the absence of these risk behaviors, a person classified as having AIDS due to heterosexual transmission must either report heterosexual contact with a person known to be infected or at risk for infection (i.e., someone in one of the above risk groups, an HIV-infected transfusion recipient, or a person born in a Caribbean or African country designated by the World Health Organization as "Pattern II"). Nearly all people in the United States with reported AIDS attributed to heterosexual transmission who were born in these countries were born in Haiti (1,233 of 1,253). A person with AIDS reporting heterosexual contact with a prostitute but no other risk factor is classified as having no identified risk, not as a heterosexual transmission case.

As a result of the hierarchical classification, some cases attributed to other exposures (especially IVDU) could actually have resulted from heterosexual contact. Follow-up has shown that some cases initially classified as having no identified risk actually resulted from heterosexual exposure.[7] Of course, some cases designated as "reported heterosexual contact" may have other risk factors, such as unreported homosexual contact or IVDU.

For each AIDS case, the surveillance data include the diseases recorded at the time of diagnosis, but additional diseases that develop later are not necessarily reported. This could affect time trends of the percent of cases with a disease, such as Kaposi's sarcoma (KS). For example, if wasting syndrome tends to develop earlier in the course of HIV disease than KS, the addition of wasting syndrome to the AIDS surveillance definition in 1987 would tend to decrease the percent of reported cases with KS.

ACKNOWLEDGMENTS

We thank Drs. Mary Chamberland, James Buehler, Helene Gayle, Meade Morgan, and James Curran of CDC for critical review and advice on this manuscript.

New NCHS Report Summarizes 1987 Divorce Statistics

The National Center for Health Statistics has issued a new report giving the final United States divorce data for 1987, and showing that the divorce rate (for 1,166,000 divorces) dropped 1 percent from the previous year, and was down 4 percent from the record high of 1,213,000 reached in 1981. Several measures of divorce have declined to levels of the 1970s:

- The divorce rate for 1987 was 4.8 per 1,000 population; provisional data for 1989 show a further decline to 4.7.
- The number of children involved in divorce was 1,038,000 in 1987, fewer than in any year since 1973 and reflecting both the declining number of divorces and the shrinking size of American families.

In other findings, the study reported that:

- 52 percent of divorcing couples had children under 18 years of age.
- 12 percent of those married less than a year had children, as did 26 percent of those married 1–2 years; 42 percent of those married 3–4 years; 60 percent of those married 5–9 years, and 75 percent of those married 10–14 years.
- Divorcing men and women who were college graduates had fewer minor children than couples with less education.
- Husbands and wives divorcing in 1987 were older than their counterparts in any year since 1970, reflecting longer durations of first marriages and marrying at older ages.
- For both sexes, divorce in 1987 is concentrated between 20 and 45 years of age: 81 percent of husbands and 87 percent of wives were under age 45; only 3 percent of husbands and 2 percent of wives were age 60 or over.
- In 1987, 72 percent of divorces were ending first marriages, 21 percent ending second marriages, and 7 percent ending third or higher order marriages. The average age of men ending first marriages was 34.6 years. Typically, women were 2–4 years younger, depending on the number of times they were married.

The summary report is published by NCHS as *Advance report of final divorce statistics, 1987,* in Monthly Vital Statistics Report 1990;38(12), suppl 2. Hyattsville, MD, USPHS. The full report will be published in *Vital Statistics of the United States, Vol III—Marriage and Divorce*. Patient 'Dumping' Post-COBRA

ARTHUR L. KELLERMANN, MD, MPH, AND BELA B. HACKMAN, MD

Abstract: To gauge the impact of the new federal patient transfer provisions following the federal Combined Budget Reconciliation Act of 1985 (COBRA), we monitored all emergency interhospital transfers to a public hospital emergency department in the Memphis, Tennessee area during three identical time periods: June 1 to August 31 of 1986, 1987, and 1988. A high number of transfers in the summer of 1986 diminished only slightly in summer 1987 (following implementation of COBRA). Far greater reductions occurred in summer 1988, when overcrowding forced our hospital to refuse most transfers. In contrast to changes in hospital policy, COBRA alone had little effect in this area. (*Am J Public Health* 1990; 80:864–867.)

Introduction

On August 1, 1986 the patient transfer provisions of the federal Combined Budget Reconciliation Act of 1985 (COBRA) became law.[1] Under COBRA, hospitals receiving Medicare funds are required to take certain steps prior to transferring unstable patients or women in active labor. Although COBRA is primarily intended to stop the inappropriate transfer of unstable patients for economic reasons (a practice known as patient "dumping"), the impact of this law is unclear.[2] To study the effect of COBRA in our community, we identified all patients transferred to our public hospital emergency department during the summer months of 1986, 1987, and 1988.

Methods

Shelby County, Tennessee contains the city of Memphis (1985 population 635,000) and is surrounded by rural west Tennessee, northern Mississippi, and eastern Arkansas. The county's population is 54.5 percent White and 44.5 percent Black, with small Asian and Hispanic minorities. One of 10 general hospitals in the county, the Regional Medical Center at Memphis receives an annual operating subsidy from Shelby County government to treat county residents who otherwise cannot afford care. No other hospital for adults in Shelby County receives county funds.[3]

During each of three study intervals, June 1–August 31 of 1986, 1987, and 1988, we identified all patients transferred to the Medical Center Emergency Department from area hospital emergency departments or their affiliated free-standing emergency centers. Patients sent directly to one of the Medical Center's special care units (Level 1 Trauma Center, Burn Unit, and High-Risk Obstetric Service) were assumed to represent tertiary care referrals and were excluded.

Transfers were considered "authorized" if the sending facility contacted a physician at the Medical Center who accepted the patient prior to transfer. Patients sent without prior notification, patients sent despite the Medical Center's refusal to accept the transfer, and patients in route prior to the transfer request were considered to be "unauthorized." Transfers were judged to have been made for primarily economic reasons when "no money" or "Shelby County indigent" was explicitly identified by the sending physician as the primary reason for transfer or no specific reason for transfer was recorded but the patient lacked private insurance, Medicare, or Medicaid. Unstable patients were identified by three independent reviewers who compared each patient's chart to a previously published[3] list of explicit criteria (see Appendix). Only patients meeting one or more criteria in the judgment of all three reviewers were considered to be unstable at the time of transfer.

COBRA became law on August 1, 1986 but no immediate changes in local hospital policy occurred at that time. However, in October 1986, local news stories[4–6] and subsequent state[7] and federal[8] hearings focused increasing attention on patient "dumping." Telephone screening of transfer requests was also intensified, but our long-standing practice of accepting indigent patients deemed "stable" for transfer did not change. Although hospital over-crowding intermittently required us to restrict interhospital transfers during 1986 and 1987, these intervals were generally brief. By the summer of 1988, however, overcrowding became so severe that the Medical Center Emergency Department (ED) was repeatedly forced to restrict authorization of interhospital transfers for days at a time. No other major changes in health policy occurred in Memphis during this time (Table 1).

TABLE 1—Study Interval Characteristics

	Summer 1986	Summer 1987	Summer 1988
Time Interval	92 days	92 days	92 days
Total ED Visits	15,617	17,355	18,220
COBRA in Effect?	No*	Yes	Yes
Hospital Crowding	Moderate	Moderate	Severe
Total Days Transfers to Medical Center ED Restricted**	31 days	36 days	65 days

*COBRA implemented 8/1/86; law not widely recognized until fall of 1986.
**Authorizations restricted all or part of a calendar day.

Results

During summer 1986, 266 patients were transferred to the Medical Center ED, 243 of which (91 percent) were sent for primarily economic reasons. Somewhat fewer patients (N = 226) were transferred during summer 1987, (when COBRA was in full effect), but the proportion sent for primarily economic reasons did not change. Under the severely overcrowded conditions of summer 1988, total interhospital transfers declined precipitously (N = 85), but the proportion sent for primarily economic reasons remained the same (92 percent).

More than half of patients transferred during the summer of 1986 were unauthorized, including four sent despite refusal by the Medical Center. During summer of 1987 (post COBRA) unauthorized transfers declined by only 18 percent, but 10 patients were sent despite refusal by the Medical Center. During summer 1988, unauthorized transfers declined by fully 61 percent compared to 1986; five transfers arrived despite prior refusal by the Medical Center (Figure 1).

COBRA is intended to stop the inappropriate transfer of unstable patients, particularly when transfer is being accomplished for primarily economic reasons.[2] Based on explicit criteria, 64 of 243 patients (26 percent) transferred to the Medical Center primarily for economic reasons during the summer of 1986 were determined to be unstable. Two of every three had been accepted as "stable for transfer" on the basis of telephone assurances by the sending physician.[3] Unstable economic transfers fell modestly in the summer of 1987 (N = 46) and declined sharply in summer 1988 (N = 13) but the proportion sent without advance authorization did not change. Virtually identical numbers of economic transfers required emergency hospitalization during the summers of 1986 and 1987, and the number requiring emergency surgery and/or intensive care actually increased. Both total admissions and total critical care cases fell sharply during the summer of 1988 (Figure 2). Seven transferred patients died

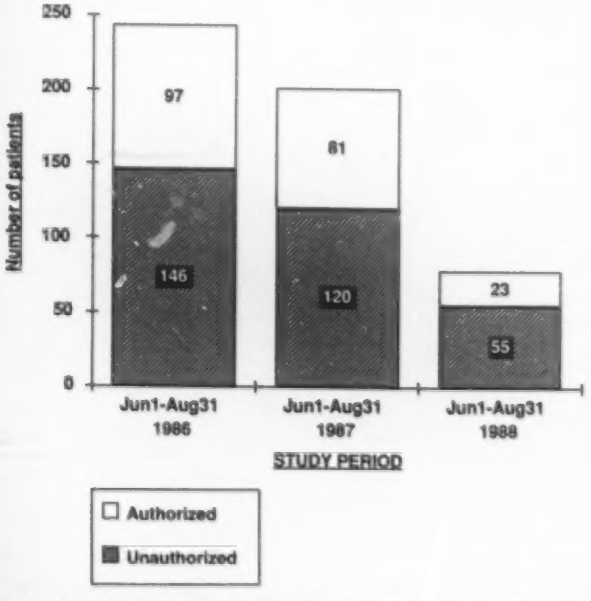

FIGURE 1—Authorized vs Unauthorized Economic Transfers to Memphis Medical Center, Summer 1986, 1987, 1988

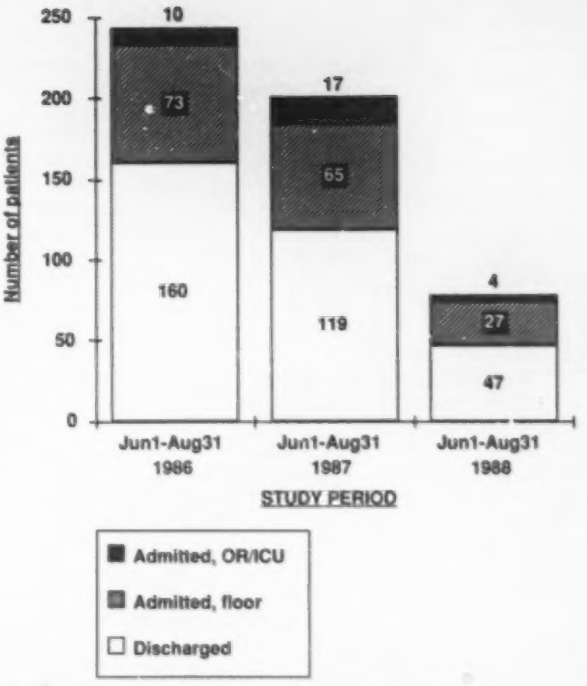

FIGURE 2—Disposition of Economic Transfers Made to Memphis Medical Center Emergency Department, Summer 1986, 1987, 1988

prior to hospital discharge during one of the three study periods: three in summer 1986, three in summer 1987, and one in summer 1988. None of these had been sent without advance authorization by the Medical Center.

Discussion

In 1988, an audit by the Office of Inspector General for the Health Care Financing Administration found that record keeping at most sending hospitals is inadequate to monitor patient transfers in general, much less to screen for "dumping," and that few receiving hospitals have a procedure for identifying potential violations of COBRA. With no effective mechanism for monitoring transfers, the report concluded that ". . . the ability of HHS (Department of Health and Human Services) to monitor and oversee this (dumping) problem is jeopardized. . ."[9]

By documenting interhospital transfers to a single public hospital, we were able to study community practice before and after implementation of COBRA. Explicit criteria were devised and consistently applied throughout each of three identical study intervals. Definitions of "unstable cases" and "economic transfers" were narrowly drawn. As a result, our case totals are almost certainly conservative. For example, all obstetric, burn, and trauma center transfers were presumed to represent tertiary care referrals, even when the patient was indigent and his or her problem could have been easily managed at the original hospital.

Four limitations to our study warrant comment. First, given the case mix of our emergency department, we cannot address COBRA's impact on transfers of children or of women in labor. Second, our data are based on temporal associations between changes in national (and local) health

care policy and changes in the number and types of patients transferred to our emergency department. Although no major changes to Shelby County's health care system occurred during the time period studied, we cannot exclude possible effects of other, unidentified factors. Third, without access to the charts of indigent patients seen at other hospitals, we cannot judge whether they were better or worse off when transfers to our hospital were restricted. We believe that most who would otherwise have been transferred to the Medical Center were either admitted or adequately treated at the original hospital, since few found their way to our emergency department the following day. Finally, our conclusions are based on transfers to a single public hospital. They may not reflect COBRA's effect on patient "dumping" in other cities or states.

In an era of intense health care competition, the pressure on private hospitals to transfer non-paying patients to public facilities is great. We found that COBRA alone had little impact on the magnitude or nature of patient "dumping" in Memphis. Substantial reductions in total economic transfers did not occur until the Medical Center began to sharply restrict authorizations due to overcrowding. The role COBRA may have played in limiting the number of unauthorized transfers during this latter time period is unclear.

Caught between concerns about patient dumping and the need to maintain cordial multi-institutional relationships, public hospital officials are reluctant to address potential violations of COBRA.[9,10] Recently HCFA proposed stiff penalties for receiving hospitals that fail to report suspected cases of dumping.[11] Our data suggest such measures may be needed. As currently written, the impact of COBRA appears to be slight.

APPENDIX
Severity of Illness Criteria
(noted at time of arrival in receiving emergency department)

Vital Signs

a) Heart rate >140 or <50 beats per minute
b) Respiratory rate >28 or <8 breaths per minute
c) BP Diastolic <40 or >130 mm Hg
d) Temperature <94 or >102 degrees fahrenheit

Cardiovascular

a) Chest pain with suspicion of ischemia
b) Rhythm: supraventricular tachycardia with heart rate ≥149 heart block (second degree mobitz II or greater), ventricular tachycardia or high grade ectopy
c) IV antiarrhythmics or IV pressors (eg, dopamine, dobutamine, norepinephrine, lidocaine, procainamide, bretyllium) during transport

Respiratory

a) Hypoxia (PO2 ≤ 60 mm Hg regardless of FIO2)
b) Intubated prior to transfer
c) Noted to be in "respiratory distress" or "respiratory failure"
d) Airway obstruction with stridor
e) Respiratory acidosis (pH <7.30 with pCO2 >50 mg Hg)

Infections

a) Meningitis (suspected or diagnosed)
b) Sepsis (suspected or diagnosed)
c) Active infection in an immunocompromised hosts. (cancer patients, leukemia, AIDS)

Shock

a) BP <100, with tachycardia (P≥100), and/or other findings of hypoperfusion: (i.e., decreased mentation, cool extremities, dusky extremities, evidence of organ dysfunction)

Metabolic

a) Diabetic ketroacidosis (pH <7.30, HCO3 <14 mmol/l with glucose >200 mg/dl and ketonuria)
b) Hypoglycemia (BG <40 mg/dl with mental status change)
c) Hyperglycemia: (BG >800 mg/dl)
d) Potassium ≤3.0 or ≥6.0 meq/L
e) Acidosis (pH <7.30) (any cause)
f) Drug toxicity (Digoxin level >2.0 ng/ml, theophylline >20.0 mg/ml Phenytoin level >30.0 mg/ml, Lithium >2.0 mmol/l, drug screen positive of tricyclic antidepressants with suspicion of overdose)
g) Sodium >150 meq/l or <125 meq/l

Neurologic

a) Altered mental status (lethargic, confused, comatose, unable to answer questions)
b) New focal neurologic deficit(s) (all causes)

Ob/Gyn

a) Suspected ectopic pregnancy with pain and/or bleeding

Hematology

a) Severe anemia (hematocrit <25% with evidence of acute blood loss per nasogastric tube or hematemesis, rectal bleeding, and/or vaginal bleeding)
b) Required blood transfusion during or prior to transport
c) Active blood loss upon arrival of >500 cc with evidence of shock regardless of hematocrit

Gastroenterology

a) Active upper/lower GI bleeding
b) Possible acute abdomen (abdominal tenderness, with signs of acute peritonitis) or pancreatitis

ACKNOWLEDGMENTS

We are indebted to the nurses of the Regional Medical Center at Memphis Emergency Department and to the Internal Medicine residents of the University of Tennessee, Memphis for their assistance with case identification; to Dana Miller, Director of Quality Assurance at the MED for her assistance with chart review; to Maxine Smith for copying and maintenance of transfer case files; and to Carol Conway for data entry and manuscript preparation.

This work was supported in part by the Administration of the Regional Medical Center at Memphis. The views expressed are those of the authors and do not necessarily reflect those of the University of Tennessee or the Regional Medical Center at Memphis.

This study was presented before the 116th annual meeting of the American Public Health Association in Boston, Massachusetts, November 18, 1988.

Serious Poisonings among Older Adults: A Study of Hospitalization and Mortality Rates in Massachusetts 1983–85

ALAN WOOLF, MD, MPH, SUSAN FISH, PHARMD, CAREY AZZARA, MA, AND DEBORAH DEAN, MSPH

Abstract: We analyzed poisoning-related hospitalization and mortality rates among older adults living in Massachusetts during 1983–85. While poisoning-related hospitalization rates of individuals ≥60 years were near the state average, death rates for men ≥70 years and for women over 60 were higher than those of younger individuals. Medications and carbon monoxide were commonly implicated agents in these poisoning deaths. Older adults are more vulnerable to death from a poisoning than are younger age groups. (*Am J Public Health* 1990; 80:867–869.)

Introduction

The incidence of serious poisonings among older individuals is poorly documented. The purpose of this study was to determine poisoning hospitalization and death rates among older people in Massachusetts, and to compare such rates with those of younger age groups in order to assess relative risk.

Methods

The Massachusetts Uniform Hospital Discharge Data Set (UHDDS) contains all hospital discharges recorded by 108 acute care institutions within the state. Data from 1983–85 were scanned for principal discharge diagnoses recorded as poisonings or adverse effects of chemicals or drugs. The International Classification of Diseases, 9th edition, Clinical Modification (ICD-9-CM) diagnosis codes used in the analysis are shown in the Appendix. Data were aggregated by five-year age intervals and sex. Death certificates for 1983–85 constituted our second data set. A death was counted as due to poisoning if either the underlying cause of death or any mentioned cause was listed as a poisoning or adverse effect of a drug or chemical. Rates were calculated based on population estimates for 1985 made by the Massachusetts Institute for Social and Economic Research.[1] Hospitalizations and deaths due to the acute or chronic effects of alcoholism were specifically excluded. Age- and sex-specific poisoning-related hospitalization rates and death rates were calculated and compared with mean statewide rates.

Results

Hospitalization

There were 17,805 hospitalizations in Massachusetts during 1983–85 in which a poisoning or the toxic effect of a drug or chemical was the principal discharge diagnosis; 2,200 of these involved persons 60 or more years of age. Almost 81 percent (N = 1778) of the hospitalizations of persons 60 or more years of age were associated with exposures to medications; household products were implicated in 301 (13.7 percent); plant exposures, animal stings or envenomations were implicated in 121 (5.5 percent). The poisoning hospitalization rates and 95% confidence intervals for both males and females in all age groups between 60–79 years were below the state average for persons under age 60 (Table 1). The poisoning hospitalization rates for males age 80 and older were higher than the state average for males under age 60.

Deaths

There were 1,116 deaths attributable to poisonings or toxic effects recorded in Massachusetts during the years 1983–85, including 136 male and 139 female deaths of persons 60 or more years of age. Death rates from poisoning for males 70 or more years of age and for females 60 or more years of age were substantially higher than the sex-specific state rates

TABLE 1—Annualized Poisoning Hospitalization Rates and Relative Risks,* Massachusetts 1983–85

Age Groups (years)	Males (Hosp/10^5/Yr)	RR* (95% CI)	Females (Hosp/10^5/Yr)	RR* (95% CI)
60–64	44	.47 (.40, .55)	58	.47 (.42, .53)
65–69	57	.61 (.52, .70)	64	.52 (.46, .58)
70–74	58	.62 (.52, .73)	74	.60 (.52, .67)
75–79	64	.68 (.56, .83)	91	.73 (.65, .83)
80–84	116	1.23 (1.01, 1.50)	102	.82 (.72, .95)

for persons under 60 years of age with relative risks increasing directly with age (Table 2).

For 152 of the original 275 poisoning-related deaths of persons 60 or more years of age, E-coded data were available enabling assessment of intentionality (Table 3). For both males and females, drugs were the most important agent of accidental (unintentional) death. Carbon monoxide was a common cause of intentional (suicidal) poisoning-related death in males but drugs predominated among females.

Discussion

Seniors might be considered to be at a higher risk for a serious poisoning incident than adults in younger age groups for a variety of reasons. While the elderly comprise just 12 percent of the total population, they consume 31 percent of all prescription medications.[2] It is common for elders to be taking multiple medications simultaneously.[3–6] Many have underlying heart, liver, kidney, or lung diseases, any of which might complicate an overdose situation or affect the pharmacokinetics of a drug or toxin.[7–9] Also, 2–4 million older Americans suffer from dementia[10]; such patients may be confused and have difficulty complying with complicated dosage regimens. Failing eyesight and memory may be responsible for medication errors or for mistaking household products as potables. Finally, the elderly are at risk for depression[11] and may take overdoses in suicide attempts.

Previous analyses of calls to Poison Control have concluded that the poisoned elderly are more likely to be admitted to the hospital and are more likely to die from the poisoning than are younger age groups.[12,13] However small numbers of subjects, a lack of population-based denominators, and an acknowledged reporting bias raise questions regarding the validity of such findings. The current study suggests that hospitalization rates for poisoning among older adults are not very different from those of younger age groups. However, our results support the conclusion that both elderly males and females are at greater risk of poisoning-related death than younger persons. That older individuals are more vulnerable to a terminal outcome from a poisoning episode reinforces the speculation that they are more fragile to the toxic effects of drugs and poisons than are younger individuals. Also, E-coding analysis suggests suicide to be a prominent cause of poisoning death among the elderly. These two factors, vulnerability and intentionality, are important considerations for both clinicians and researchers studying poisoning in this age group.

TABLE 2—Annualized Poisoning-Related Death Rates and Relative Risks,* Massachusetts 1983–85

Age Group (years)	Males (Deaths/ 10^5/Yr)	RR* (95% CI)	Females (Deaths/ 10^5/Yr)	RR* (95% CI)
60–64	8.34	1.04 (.73, 1.48)	6.62	1.74 (1.20, 2.22)
65–69	7.45	0.93 (.62, 1.40)	7.04	1.85 (1.26, 2.70)
70–74	14.43	1.80 (1.27, 2.55)	5.68	1.49 (.95, 2.34)
75–79	13.07	1.63 (1.04, 2.55)	7.79	2.04 (1.32, 3.15)
80–84	14.00	1.75 (.99, 3.09)	6.07	1.59 (.89, 2.84)
85+	20.54	2.56 (1.48, 4.44)	13.07	3.43 (2.28, 5.16)
State Average (all ages)	9.37		5.16	
State Average (persons less than 60 years old)	8.02		3.81	

*RR = Relative Risk (Age Specific Rate/State Average [<60 yr]). 95% confidence intervals in parentheses.

ACKNOWLEDGMENTS

This research was supported, in part, by a grant from the New England Injury Prevention Research Center. This paper was reported, in part, at the 117th annual meeting of the American Public Health Association, in Chicago, Illinois on October 26, 1989, and in part, at the Annual Meeting of the American Association of Poison Control Centers, Baltimore, Maryland, October 4, 1988. We acknowledge with gratitude the statistical assistance of Dr. Terry Fenton.

APPENDIX

ICD 9-CM Diagnosis Codes Used in Dataset Analysis

960-979.9	Poisonings by drugs, medicinal and biological substances
980-989.9	Adverse effects of drugs
E850-E858.9	Accidental poisoning by drugs, medicinal substances, and biologicals
E860-E869.9	Accidental poisonings by other solid and liquid substances, gases, and vapors
E950-E952.9	Suicide and self-inflicted poisoning
E962.0	Assault by poisoning
E980-E980.5	Injury undetermined whether accidentally or purposefully inflicted by poisoning

(E coding refers to the circumstances under which poisoning or injury occurs)

Changes in Ambulatory Surgery Utilization 1983–88: A Community-Based Analysis

RONALD J. LAGOE, PHD, AND JOHN H. MILLIREN, PHD

Abstract: Changes in ambulatory surgery utilization in the metropolitan area of Syracuse, New York 1983–88 were identified. Total ambulatory surgery utilization rose from 12,479 to 24,643 procedures. Approximately 69 percent of the increase was generated by freestanding surgery centers. Operations responsible for the largest additional volumes included lens procedures, certain cervical procedures, hernias, and excision of skin and breast lesions. (*Am J Public Health* 1990; 80:869–871.)

Introduction

Ambulatory surgery is usually defined as procedures which are more complicated than those carried out in physicians' offices but less complex than those which necessitate inpatient hospital stays.[1] In the United States, the availability and utilization of ambulatory surgery have increased considerably during the past two decades.[2] By 1988, 964 freestanding surgery centers were operating in the nation, and hundreds of hospitals performed selected procedures on an outpatient basis.[3,4] Between 1983 and 1988, ambulatory surgery utilization nationwide increased from approximately 5,000,000 to about 13,735,000 procedures.[4,5] It has been reported that physicians no longer have to be convinced to use ambulatory surgery, they insist on it.[6]

Changes in the health care marketplace have also encouraged the growth of ambulatory surgery. The introduction of prospective payment approaches by Medicare and other payors has focused on reduction of hospital stays. Medicare now requires that certain eye procedures be performed in outpatient settings. Reductions in inpatient utilization, brought about by these mechanisms, have encouraged hospitals to compete in a variety of settings, including ambulatory care.[2,7,8]

Evaluation of the growth of ambulatory surgery has been made difficult by the lack of consistent, longitudinal data concerning this modality.[9] The present study evaluated developments in ambulatory surgery in the metropolitan area of Syracuse, New York between 1983 and 1988 to follow up earlier reports.[10,11]

The health care system of Syracuse, New York has made extensive use of ambulatory surgery because of the limited supply of acute care beds in the area (2.9 per 1,000 population compared with 4.1/1,000 population nationally).[12,13] During 1983, four ambulatory surgery programs existed in Syracuse. One of these programs was freestanding operated by a hospital (including four operating rooms), the others were hospital-integrated (using existing institutional operating rooms and support services). Between 1983 and 1988, two additional freestanding programs were opened in Syracuse. One of these was an additional program operated by Crouse Irving Memorial Hospital, the other was established by a group of local physicians.

Methods

This study identified changes in ambulatory surgery utilization in Syracuse between 1983 and 1988 at the aggregate and procedure-specific levels. Aggregate data for ambulatory surgery were obtained from the hospitals. Procedure-specific data were collected from two hospitals, Crouse Irving Memorial Hospital and St. Joseph's Hospital Health Center, which maintained such information for both years. Inpatient data for the same procedures were obtained from New York's Statewide Planning and Research Cooperative System.

Results

Between 1980 and 1987, the rate of inpatient surgical operations per 1,000 population in the United States declined from 78.1 to 76.4.[14] The data in Table 1 demonstrate that, between 1983 and 1987, discharges of surgical patients per 1,000 population declined in all six of New York State's major metropolitan areas. The largest decline (16.0 discharges per 1,000 population or 25.4 percent of the 1983 level) was produced in Binghamton. Syracuse, which in 1983 had a rate lower than all of the other areas, was able to reduce that rate by 10 percent within a five-year period.

The data in Table 2 indicate that the total procedures performed in ambulatory surgery programs in Syracuse increased by 97.5 percent during the five-year period. This was paralleled by an estimated 150 percent increase at the national level.[8,4] The total ambulatory procedures performed in Syracuse during 1988 (24,643) exceeded the number of

TABLE 2—Ambulatory Surgery Utilization, Syracuse, New York, 1983–88

Facility	Ambulatory Surgery Procedures		
	1983	1988	Percentage Increase
Community-General Hospital	1,519	3,223	112.2
Crouse Irving Memorial Hospital Total	8,104	12,699	56.7
(Irving Avenue Site)	(8,104)	(8,646)	
(Madison-Irving Site)	(0)	(4,053)	
St. Joseph's Hospital Health Center	2,118	2,895	36.7
University Hospital of the SUNY Health Science Center at Syracuse	738	2,061	182.0
Harrison Center	0	3,746	—
Total	12,479	24,644	97.5

principal inpatient operations performed in hospitals (19,075).

Increased use of ambulatory surgery in Syracuse reflected developments at most programs in the community. Freestanding centers operated by Crouse Irving Memorial Hospital and Harrison Center accounted for 68.6 percent of the total increase of 12,164 procedures. Utilization of the hospital integrated programs operated by Community-General Hospital, St. Joseph's Hospital Health Center, and University Hospital also increased, but absolute changes in volume at these facilities were smaller.

Detailed diagnostic data are available for 1983 and 1988 only for procedures performed at the freestanding program operated by Crouse Irving Memorial Hospital and the hospital integrated program managed by St. Joseph's Hospital Health Center.

The freestanding model at Crouse Irving Memorial Hospital was able to generate greater volumes of individual ambulatory surgery procedures. Most of the specific procedures carried out at this hospital were performed in the freestanding model rather than on an inpatient basis (data available on request to authors). With the exception of rhinoplasties and inguinal hernia repairs, more than 90 percent of all of the procedures identified in Table 3 were performed at Crouse Irving Memorial Hospital on an outpatient basis. It was also notable that the percentage of rhinoplasties carried out on an outpatient basis increased from 28 to 81 and the percent of inguinal hernia repairs rose from 49 to 68. These procedures have proven to be useful indicators of the extent of ambulatory surgery utilization.

The hospital-integrated program at St. Joseph's was also able to increase ambulatory surgery volumes but, at the absolute level, these increases were considerably smaller than those which occurred in the freestanding program. By comparison, in 1988, approximately 80 percent of rhinoplasties and 12 percent of inguinal hernia repairs at this hospital were being performed on an outpatient basis. These trends have caused St. Joseph's Hospital Health Center to plan the development of its own freestanding program.

Hip Fracture Incidence among the Old and Very Old: A Population-Based Study of 745,435 Cases

STEVEN J. JACOBSEN, MS, PHD, JACK GOLDBERG, PHD, TONI P. MILES, MD, PHD, JACOB A. BRODY, MD, WILLIAM STIERS, PHD, AND ALFRED A. RIMM, PHD

Abstract: Data were obtained from the Health Care Financing Administration and the Department of Veterans Affairs (formerly called Veterans Administration) on all hospital discharges among the elderly population from 1984 through 1987 and combined with census estimates to calculate incidence rates of hip fracture for the elderly population of the United States. Rates for White women were the highest, reaching 35.4 per 1,000 per year among 95 year-olds. Comparably, White men, Black women, and Black men experienced similar age-related increases in risk, although of less magnitude and relatively less rate of change, respectively. (*Am J Public Health* 1990; 80:871–873.)

Introduction

Hip fractures are an important cause of the morbidity and mortality experienced by the elderly population in the United States.[1] Despite this, there have been relatively few national population-based studies of the incidence of hip fracture in this country. Of those previous studies, most have produced unstable estimates of incidence rates for non-Whites (due to small sample sizes)[2,3] or the oldest old (over 85 years of age).[2–7] The present study uses newly available data from the Health Care Financing Administration (HCFA) and the Department of Veterans Affairs (VA) to provide detailed estimates of the incidence of hip fracture in the elderly by age, race, and sex.

Address reprint requests to Steven J. Jacobsen, PhD, Division of Biostatistics/Clinical Epidemiology, Medical College of Wisconsin, P.O. Box 26509, Milwaukee, WI 53226. This work was done while Dr. Jacobsen (currently a third-year medical student at Medical College of Wisconsin) was completing the doctoral requirements in the Epidemiology Program, School of Public Health, University of Illinois at Chicago. Drs. Goldberg and Miles are both with the Epidemiology/Biostatistics Program there, and Dr. Brody is Dean of the School of Public Health, University of Illinois, Chicago; Dr. Stiers is with Health Services Research and Development, VA Hospital, Hines, IL; Dr. Rimm is Professor and Head, Division of Biostatistics/Clinical Epidemiology, Medical College of Wisconsin, Milwaukee. This paper, submitted to the Journal June 19, 1989, was revised and accepted for publication October 17, 1989.

© 1990 American Journal of Public Health 0090-0036/90$1.50

Methods

Data were obtained from HCFA on all 40 million short-stay hospital discharges for the calendar years 1984 through 1987 and 4 million discharges from VA hospitals. HCFA requires all institutional providers to submit a uniform billing form that contains the following data: age, race, sex, a maximum of five ICD9-CM diagnostic categories, date of admission and discharge, and a unique patient identifier. VA maintains a similar database, keyed by the same patient identifier.

Cases of hip fracture were identified by scanning the 44 million discharge records for a discharge diagnosis of fracture of the hip (ICD9-CM 820.0 through 820.9) in any of the five diagnostic fields. Patients were excluded if: 1) age at admission was less than 65 years; 2) the fracture could have been attributed to a neoplastic process; 3) the patient had been discharged previously for fracture of the hip in the four-year period; 4) the first discharge diagnosis was for late effects of fracture; or 5) the patient resided outside of Puerto Rico or the United States proper. The remaining cases were considered to be first fractures of the hip and thus comprised the numerator for the calculation of rates.

Denominator information was obtained from the Bureau of the Census for 1985. Incidence rates were calculated as the average annual age-, race-, and sex-specific number of cases divided by the population at risk. Rates were adjusted for one-year age groups using the direct method, with the entire United States population aged 65 years and older serving as the standard.[8]

Results

During the period of 1984 through 1987, 810,949 hospital discharges for fracture of the hip were recorded by HCFA and 11,435 were recorded by VA for persons over 65 years of age. Of these, 54,055 were second fractures or rehospitalizations for a previous hip fracture. An additional 19,899 cases were persons under the age of 65 from the HCFA database, and 4,504 cases were discharged for late effects or attributable to neoplastic processes. The final number of eligible incident cases of first hip fracture was 745,435. (Some cases were excluded for more than one reason.) Women accounted

for 580,129 of these fractures (79 percent) whereas men accounted for only 165,306 (21 percent) (Table 1). The great majority of the cases were among Whites (93 percent), while Blacks and those of other or unknown racial background each accounted for 3 percent.

The incidence of hip fracture among the elderly for this time period was 6.63 fractures per 1,000 per year. Adjusting incidence rates for age, White women experienced the highest incidence rates at 8.07 per 1,000, followed by White men at 4.28/1,000, Black women at 3.06/1,000, and Black men at 2.38/1,000. Examining incidence rates by one year age groups (Figure 1) shows that rates for White women increased exponentially from 1.63/1,000 in 65 year-olds, to 35.4/1,000 in women aged 95 years. A similar exponential pattern of increase was observed for White males, with rates increasing from 0.9/1,000 for 65-year-olds to 26.0/1,000 for 96-year-olds. The age-associated increase in incidence persisted in Blacks, but was less than exponential in women and nearly linear in men.

Discussion

The risk of fracture of the hip increased with age well into the tenth decade of life for women and men, and Blacks and Whites alike. Incidence rates for White women between the ages of 85 and 95 were especially high, with more than 3 percent of this population suffering a fracture of the hip. White men, Black women, and Black men also suffered from high rates of injury, with rates reaching nearly 3, 2, and 1 percent of the nonagenarians, respectively.

The rates for White men and women calculated in this study resemble those reported from the Scandinavian countries,[9–11] except that rates in the oldest women appear to be higher in Sweden.[11] Estimates from Rochester, Minnesota appear to underestimate rates for both men and women over the age of 80 years,[5–7] but this may be due to small sample sizes. It is noteworthy that our results substantiate prior national estimates using data from the National Hospital Discharge Survey for all race and age groups,[2,4,12] despite the previously noted problems with similar data.[13]

SOURCES: Health Care Financing Administration, Department of Veterans Affairs, US Bureau of Census.

There are several limitations in these data. The assumption that all fractures of the hip necessarily result in hospitalization is probably valid, because hip fractures are associated with a great deal of pain and incapacity; but persons who did not survive long enough to be hospitalized would be missed. A second assumption is that persons hospitalized in this age range are covered by the Medicare insurance program or cared for in VA hospitals. According to the Health Care Financing Administration,[14] 97 percent of the United States population ages 65 and older is enrolled in the Medicare program. The number of cases treated in VA hospitals appears to account for the vast majority of the remaining 3 percent, suggesting these rates reflect true population rates.

These data may over-estimate the risk of an incident first fracture since data are only available for up to four years of follow-up. The rates presented herein may represent up to a 6 percent over-estimate of the risk of a first fracture. Likewise, the use of these data to estimate the prevalence of fracture would result in an underestimate for the same reason.

The apparent decline in fracture incidence after age 95 among white women is intriguing. Possibly, women who are at risk of fracture have been removed from the population through fracture-related mortality or competing causes. It is noteworthy that this decline persists when all fractures during the four years of follow-up are included in the numerator. Alternatively, this result may reflect some degree of non-sampling error inherent to the data. Only more detailed surveillance of an elderly population will provide the opportunity to ascertain the meaning of the decline.

ACKNOWLEDGMENTS

The data were presented at the Steenbock Symposium on Osteoporosis in Madison, WI, June 1989 and the 117th Annual Meeting of the American Public Health Association, in Chicago, Illinois, October 1989. This work was completed with the cooperation of the Health Care Financing Administration.

Swaddling and Acute Respiratory Infections

KADRIYE YURDAKOK, MD, TUNA YAVUZ, MD, AND CARL E. TAYLOR, MD, DRPH

Abstract: In Turkey and China the ancient practice of swaddling is still commonly practiced. Both countries have extremely high rates of pneumonia, especially during the neonatal period. Preliminary evidence on the possibility that swaddling may interfere with normal respiratory function and thereby predispose to pneumonia was gathered in a teaching health center in Ankara. Babies who had been swaddled for at least three months were four times more likely to have developed pneumonia (confirmed radiologically) and upper respiratory infections than babies who were unswaddled. These preliminary findings were highly significant and are being followed up by further studies. (*Am J Public Health* 1990; 80:873–875.)

Introduction

The ancient practice of swaddling has almost disappeared in most countries of the world. A national sample survey in Turkey, however, showed that 93 percent of mothers swaddle their children.[1] In China also, most babies are tightly swaddled from birth through the first several months of life.[2] Since these two countries include over one-fifth of the children of the world, the number of swaddled babies is substantial.

In both countries pneumonia is the first cause of death among children, with particularly high incidence among neonates. In Turkey about 50,000 infant deaths occur annually due to pneumonia.[3] In China over 300,000 child deaths per year are attributed to pneumonia with a child mortality rate twice as high as the second highest cause of death.[4] Forty percent of these deaths are under one month of age.

In trying to explain this extremely high incidence of pneumonia we focused on the possibility that swaddling might interfere with normal respiratory function and lung expansion. No studies have been published of possible relationships between swaddling and acute respiratory infections or pneumonia.

The common cultural practice is that immediately after birth babies are tightly bound in layers of cloth. Complete swaddling immobilizes the baby from the neck to the feet. The legs are pressed firmly together with the knees straight and the arms are bound to the sides or slightly to the front of the body. The layers of cloth are not only pulled tightly but they are also securely tied to minimize body movement. In partial swaddling cloth is wrapped around the legs and torso up to the armpits, but the arms are free. In both types of swaddling the child may also be covered with netting or a blanket to prevent exposure to flies, drafts or cold air. Babies are almost always laid on their backs and kept in a dark room to induce sleep.[5] Swaddled babies seldom cry and respirations seem shallow to an observer, raising the question of whether full expansion of the lungs occurs. A variety of devices are used to dispose of excreta in Turkey but in the urban area where this study was done families use cloth diapers.

Methods

The records from Gulveren Health Center in a suburb of Ankara were examined to look for associations between swaddling and selected health problems. This teaching health center of Hacettepe Medical School has high standards of follow-up and care of all the children in the health center area. Records were available on 186 infants, of whom 94 had been unswaddled, 29 had been partially swaddled, and 63 had been completely swaddled. The rate of swaddling is lower than the national figure because this study included only those babies who were swaddled for at least three months.

All infants were examined and detailed histories were taken. The ages of the children at the time of this cross-sectional study ranged from three to 12 months, with a mean of 6.8 months. Sex ratios were similar in all groups as shown

in Table 1. The mothers ranged in age between 21 and 25 years and literacy levels in the three groups were 84, 88, and 89 percent. The average number of people in each household was 5.0 in the unswaddled group, 4.81 in partially swaddled, and 5.47 in the completely swaddled group. Families were all from the same socioeconomic levels with most fathers employed in industrial plants in Ankara and approximately 11 percent unemployed in each group.

Body weights and developmental stages were similar in all groups. The history included careful questioning about respiratory infections; having more than two infections during the period up to examination was classified as frequent upper respiratory infections. Physical examination included observation for signs of rickets and congenital dislocation of the hip.

All children had been followed at the health center by midwives with high compliance for regularly scheduled clinic and home visits. If illness occurred, babies were usually brought to the health center. At the time of regularly scheduled visits, parents were also asked about illnesses treated elsewhere. All of this information was filled in on follow-up records. If the baby had special tests at a hospital, the laboratory and x-ray records were obtained and transferred to the follow-up cards. History of respiratory infections was included in this analysis only if the diagnosis had been recorded on the baby's follow-up records. A diagnosis of pneumonia was made only when clinical records showed cough, fever, and crepitations. All pneumonia cases had positive x-rays at the time of illness which were reviewed again as part of this study. Some had respiratory distress but none required hospitalization.

Results

Table 1 shows the frequency of respiratory illnesses identified in these infants. Pneumonia and a history of at least two upper respiratory infections were each about four times more common in swaddled than unswaddled babies. The association with partial swaddling was as strong as with complete swaddling and these groups were combined for statistical testing.

Discussion

Few studies have been done of the effects of swaddling. Lipton,[6] *et al*, reported that swaddling reduces motor activity and encourages the baby to sleep. Chisholm[7] confirmed these findings about motor activity and sleep and also reported less response to stimulation and less variation in heart rate. A report from Beijing[8] compared transcutaneous oxygen tension in 40 neonates with moderate pneumonia, confirmed radiologically, who were observed for periods when they were swaddled and unswaddled and placed in prone and supine positions. Measurements were made 30 minutes after feeding when the infant was asleep. Unswaddled babies in the prone position had oxygen tension 18 percent higher than swaddled supine babies and 12 percent higher than unswaddled supine babies. Several studies have shown that babies in the prone position have improved respiratory function when compared with babies in the supine position.[9,10] It may be that a combination of swaddling and the supine position produces the greatest effect on respiratory ventilation.

Rickets was more common in swaddled babies than in unswaddled babies presumably because of lack of exposure to sunlight. In Israel, Block reported an association between swaddling and congenital dislocation of the hip[11] and similar results were reported among Navajo babies bound to cradle boards.[12] No such association was found in this series of cases.

The extremely high mortality and morbidity from neonatal and infant pneumonia in China and Turkey is being further investigated by prospective studies which will provide more precise information on time relationships between swaddling and pneumonia. If a causal relationship can be defined, educational efforts can try to modify this traditional practice. The possible advantages of swaddling should also be studied since parents say that a swaddled baby child is easy to care for because it is quiet and sleeping most of the time.

TABLE 1—Swaddling, Pneumonia and Respiratory Infections in Turkey

	Unswaddled (n:94)	Partially Swaddled (n:29)	Completely Swaddled (n:63)
Age (months)	7.9 ± 2.3	8.1 ± 3.3	7.4 ± 2.1
Male/Female	1.08	1.07	1.11
Number in Household	5.0	4.81	5.47
% Literacy of Mothers	84	88	89
	n %	*n* %	*n* %
Pneumonia*	3 3.2	7 24.1	8 11.6
Frequent URI*	3 3.2	4 13.8	10 14.5

*Fisher's exact test used to compare unswaddled with both groups of swaddled babies added together: for pneumonia p = .002 and for frequent upper respiratory infections p = .004.

Assessment of AIDS Knowledge, Attitudes, Behaviors, and Risk Level of Northwestern American Indians

ROBERTA L. HALL, PHD, DONI WILDER, BS, PAMELA BODENROEDER, BA, AND MICHAEL HESS, DDS

Abstract: A survey was made of 710 American Indians of Oregon, Washington, and Idaho to assess the population's knowledge, attitudes, and behaviors in respect to acquired immunodeficiency syndrome (AIDS), to estimate the population's risk, and to plan strategies to reduce it. In contrast to 3 percent of the general population, this study found 10.6 percent of male and 6.4 percent of female Pacific Northwestern American Indians in groups considered at high risk for AIDS. (*Am J Public Health* 1990; 80:875–877.)

Introduction

Assessment of the degree to which any population is at risk for infection with the human immunodeficiency virus (HIV) is difficult. The American Indian/Alaskan Native population presents a special challenge because of its heterogenous cultural roots and its dispersion within the general population. Few Native Americans who live on reservations have been included in the National Health Interview Survey (NHIS), which studies the public's knowledge and attitudes toward acquired immunodeficiency syndrome (AIDS) (Deborah Dawson, National Center for Health Statistics, personal communication, July 14, 1989).

No census exists of persons with Native American ancestry; many in rural or reservation areas do not have telephones, and are not represented in telephone surveys. Unpublished AIDS knowledge, attitudes and behavior studies include data from women clients in a WIC (Women, Infants and Children) program; a survey of health care workers in Arizona; a survey of junior college students who primarily have Indian ancestry; and a survey of health service workers who work primarily with American Indians in the San Diego, California area (Steven Helgerson, Indian Health Service, personal communication, November 7, 1989).

Current literature reports a low rate of known AIDS cases in the American Indian population, especially in comparison to other minority groups,[1–3] but data on HIV infection do not exist and current information could understate risk in this relatively small and vulnerable population. In order to assess risk and recommend appropriate educational and preventive initiatives, the Northwest Portland Area Indian Health Board conducted an extensive survey of AIDS knowledge, attitudes, and behaviors among American Indians who live in the Pacific Northwest states of Oregon, Washington, and Idaho.

Methods

The questionnaire* was adapted from an Indian Health Service form, which included many of the items on the NHIS.[4] Questions probed respondents' knowledge about AIDS, attitudes toward people with AIDS, and behaviors related to HIV transmission. The questionnaire included a number of questions on sexual behavior (number and sex of partners, degree of acquaintance with partners, age at first sexual intercourse, etc.) and on the use of various licit and illicit drugs, including alcohol. Demographic questions asked respondents to identify their age, sex, ethnic affiliation, and education, and to categorize their residence by on or off reservation, community type and size, and state and county.

The survey was administered from September 1988 through March 1989 at 24 Indian centers in Oregon, Idaho, and Washington either by a member of the staff of the Northwest Portland Area Indian Health Board or by staff at the participating agency. Sixty-six percent of respondents were surveyed at health clinics or health stations, 17 percent at tribal offices, and 17 percent at Indian educational or community agencies. Respondents include employees, persons conducting tribal business, persons seeking health care, and family members accompanying them. All respondents were asked to complete the questionnaire; anonymity was guaranteed and individuals were assured that they would not be denied any tribal service if they chose not to answer the survey, or any part of the survey.

The sample consisted of 710 persons from ages 12 to 78 with a median age of 33 years; 237, 283, and 190 respondents were from Oregon, Washington and Idaho, respectively. Women represented 73 percent of the sample (Table 1). Idaho had the largest percentage resident on a reservation (85 percent), Washington was intermediate (69 percent), and Oregon was lowest (43 percent). This percentage did not differ by sex, but fewer of the age group under age 30 resided on reservations (59 percent) than in the age group over 50 (71 percent), while the age group from 30 to 49 was intermediate (65 percent).

TABLE 1—Sample Distribution by Age, Sex, and Risk Group*

	Age Groups (years)			
	12–17	18–29	30–49	50–78
Sex	N (%)	N (%)	N (%)	N (%)
Male	21 (41.2)	49 (23.9)	73 (24.7)	33 (31.1)
Female	30 (58.8)	156 (76.1)	222 (75.3)	73 (68.9)
Total	51 (7.8)	205 (31.2)	295 (44.9)	106 (16.1)
Risk Groups	8 (22.9)	93 (48.7)	187 (66.1)	93 (90.3)
Middle	25 (71.4)	78 (40.8)	74 (26.1)	8 (7.8)
High	2 (5.7)	20 (10.5)	22 (7.8)	2 (1.9)
Total	35 (5.7)	191 (31.2)	283 (46.2)	103 (16.8)

*Fifty-three persons (7%) did not provide their age; of these, 17 also did not provide information on sexual behaviors; an additional 45 (9% altogether) indicated their age but not their sexual behavior. Percentages are based on those responding to specific questions.

Since there was no selection among persons who visit Indian agencies to use tribal services, the sample is believed to represent that population well; those who do not use these services, such as homeless individuals and those on Skid Road, may be underrepresented. The relatively large number of women in the sample is probably due to their greater use of tribal services during business hours. To control for sex and age and to allow comparison among states and with sex and age groups surveyed in the NHIS, all responses were tabulated by sex, age, and state.[5]

Six males who had sexual relations with other males and 12 males and 30 females who have taken drugs intravenously were designated as members of the high-risk group, while middle-risk group members consisted of those who had two or more sexual partners in the past year or who had been involved with a person he/she did not know well. The low-risk group consisted of all others after exclusion of 62 persons who did not answer any of the questions about sexual behavior.
